- Exercise regularly. Not only will regular exercise make you look and feel better, it also stimulates your body to build stronger, more dense bones. "Weight-bearing" activities, such as running, walking and bicycling, have a preventive effect against osteoporosis, Marcus says. Just as straining muscle helps build it up, working against gravity helps bones become thicker and sturdier.
- Don't smoke. Not only does tobacco cause cancer, emphysema and heart disease, it also causes earlier onset of menopause.

LIFE AFTER CANCER

STANFORD—
The good news: cancer, once considered fatal, is now survived by as many as 50 percent of people it strikes. The bad news: the issues and problems they come up against are often as difficult to overcome, if not more so, as the disease itself.

A group of people sit around a table. A teenaged boy, a baseball cap taking the place of a headful of hair, tells a middle-aged man he really shouldn't feel guilty because his cancer recurred. A young woman reveals she gets so angry sometimes—she has already broken two windows in her home. This evokes concern from the group; one member suggests she buy a punching bag. It's cheaper and safer, they all agree. An old man with a thick European accent adds to the conversation with a consistent stream of one-liners, most concerning his attraction to young beautiful women. "You're a dirty old man," the middle-aged man says jokingly. "I was born that way," the old man replies.

A young woman, fairly certain she's sterile from radiation, says a close girlfriend recently told her she was pregnant. "I feel really happy for her, but I feel sad, too," she confesses. "I'd like to have a baby someday." An attractive woman laughingly recalls how, one day towards the end of her treatment, she was very excited at the prospect of going shopping. She had dressed up for the occasion, complete with wig and hat to cover her head, bare from the effects of radiation. As she approached the store a gust of wind blew her hat and wig off. Instead of shopping, she crawled under a car to recover her belongings and cried all the way home. "That was the only time I ever felt like a victim," she admits.

Individuals, they vary in age, lifestyle and background. The chances of meeting under any other situation is unlikely. Yet they come, week after week, to talk openly and uninhibitedly about their hopes, dreams, fears and problems. Their unifying link? They are cancer survivors. Some are undergoing treatment, some have recently finished. Some have been free of disease for years. All share the unexpected confrontation with their own mortality and the will to live. The only people who can fully comprehend and understand the impact of that battle, they feel, are others who experience it.

So they come to support groups, the core of Stanford medical center's programs to help patients deal with the non-medical side of cancer. In addition to the groups, Stanford offers patients home health care instruction; individual counseling, a newsletter and educational materials, as well as guidance in specific areas such as estate planning and wills, employment and financial concerns. Support groups, and the whole area of helping people cope with the psychological and social impact of disease, are phenomena as new as the increasing numbers of survivors of cancer, which as recently as a decade ago was considered almost certainly fatal.

But years of medical research and experimentation with various treatment combinations, primarily surgery, radiation and drugs, have paid off. Many forms of cancer, caused by cells-gone-awry, can be conquered. It is no longer a death sentence. Some forms, such as Hodgkin's disease, a cancer of the lymphatic system, have cure rates of 85 percent for adults seven years after treatment, and as high as 96 percent for children 11 years after treatment. Some 50 percent of all cancer patients are now cured, physicians estimate. But overcoming the disease, a feat remarkable in itself, is the easy part, many patients feel. It's after treatment ends that the real battle begins.

"Everyone thinks you go to the hospital, have your tumor taken out, come home, make love to your wife and that's the end of it," says Jerry Schleimer, a 44-year-old businessman who has had two bouts with tumors in his abdomen. "It doesn't work that way. I feel like I've grown apart from my friends . . . apart from the world. There's the rest of the world and then there are cancer patients, and the two don't mix." Until his recent move back to Los Angeles, Schleimer was a regular attendant at a support group for patients whose cancers may not be curable. Other groups are geared towards patients with specific types of cancer such as breast or head and neck cancer, as well as towards couples, families and friends. There is even a support group for AIDS patients, who, with immune systems destroyed by the disease, have contracted cancer.

Susan Taylor, who was treated at Stanford in 1979 and again in 1981 for Hodgkin's disease, came to her first support group meeting about two years ago for a class project. "I remember sitting there and thinking, 'Wow! Everybody here has Hodgkin's and they all look normal.' I didn't say a word the entire first meeting," recalls the outgoing 25-year-old formerly Olympics-bound swimmer. "I just couldn't get over the fact that all these people were there."

Taylor's class has long since ended, but she has continued attending the meetings. "I knew things were wrong in my life and I couldn't pinpoint them. Going to the meetings lets me talk with others in the same situation. I can say, 'I have that problem too. What are you doing about it?' "

But they have survived! What problems could possibly overshadow life itself?

A Stanford study, supported in part by the Robert Wood Johnson Foundation, of 403 patients treated for Hodgkin's disease showed that among their concerns were perceptions of poor health, impaired energy and activity levels, impaired body image, depression, marital troubles, inability to have children, decreased sexual interest and activity, decreased work ambition and employment problems. While the study concerned one specific group of patients, the issues are universal.

When patients are first diagnosed as having cancer it's a shock, says psychiatrist Dr. David Spiegel. "But then they're very active in treatment. This gives them the sense that they're doing something to help beat it. They have daily contact and get a lot of encouragement from the staff administering treatment. But when treatment is over they get depressed. All of a sudden they're not doing anything to prevent the disease. Every lump or pain is automatically suspect. It's very painful just to sit and wait."

"Just as my doctor touches my stomach once a month to check for any lumps that may mean a recurrence, I check myself every day," Schleimer says. "I'm absolutely scared out of my mind. The last thing I want to do is die."

"When people are diagnosed as having cancer they go through the devastating experience of losing control," explains Isabel Walker, the clinical social worker who leads Schleimer's support group, among others. "They immediately have to start to regain that control. They have to learn the process of being a patient." They have to focus on what they can do, rather than on what they cannot do, she stresses. "It's making substitutions. If they used to jog, I suggest they take walks," she says. "If they're upset because they cannot work, I tell them their new job is to stay alive — probably the most difficult one they'll ever have." Many, she adds, end up making a lot of changes beginning with day-to-day activities and branching out to broader, philosophical attitudes about life.

"I was extremely self-confident from swimming and the cancer just wiped that out," Taylor says. "The support groups and going to school helped build it back up. I look at my life as a pyramid. It seems like the Hodgkin's is the base and my whole life is made of blocks stacking up on that base."

That sense of confidence is often just one factor affecting individuals' self-image and self-esteem. This is especially true for women with breast cancer who have had to undergo mastectomies. "Breasts are a symbol of femininity, of desirability," explains Dr. Regina Kriss, project director of Stanford psychiatry department's postmastectomy group therapy, who has undergone two mastectomies herself. "Without them, it's the loss of an essential part of your core of existence as a woman."

"People go through a shift in values, a change of who they are and what they want out of life once they've accepted this event that has taken place," says Pat Fobair, a clinical social worker dealing primarily with Hodgkin's patients. "The shift is definitely in favor of people instead of material things or money."

So true, agrees Schleimer, a self-described former Type A workaholic whose work days started at 6 a.m. and ended at 7 p.m., after which he'd play tournament-level racquetball. "I don't want any type of position with a lot of stress or responsibility," he says. "All I want to do now is eke out a living. Life is very short and you should enjoy every day of it.

"Through the support groups I learned that killing yourself trying to make a buck just isn't worth it," he continues. "I've adopted more of a 'smell the flowers' type of attitude."

"I'm much more willing to take risks now," admits Maria Grabowski, a 25-year-old nurse who moved to Stanford from Pittsburgh a few years ago for treatment of cancer in her pelvic region. "You don't know if you'll have another chance to do something so you live each day as if it were your last." Since being declared disease-free, Grabowski has gone hang gliding and scuba diving, for example, and is much more honest with her emotions as well. "People tell me I'm a much nicer person to be around," she says.

While many patients, like Grabowski, feel they come out of their cancer experience a better person, the emotional impact, within themselves and particularly with spouses, can be major. Studies have shown the divorce rate among cancer patients is somewhat higher than normal, Fobair says. In many instances, people can't handle the intense stress of the crisis and spouses realize their mates are not everything they may have thought, or hoped, them to be.

"The cancer has affected everything about our lives," says Schleimer's wife of 20 years, Paulette. "We've always been very, very close," Schleimer continues, "but since my recurence we seem to really be on each other's back. We're not really angry at each other, we're just angry."

What they do periodically, upon Walker's suggestion, is something called a "10-10." "We both write for 10 minutes and leave out all the superficial garbage," he explains. "Then we talk about what we wrote. What comes out is some really heavy stuff—mostly just how much we need each other."

Children too are affected when they learn that a parent has cancer. One mother recalls telling her daughter of her disease. "For the next few weeks, I heard 'I hate you, Mommy' over and over," she says. Schleimer's wife remembers that her son could not look at his father during the stage when his hair fell out from the radiation.

Taylor, who met her husband just weeks before she was diagnosed, feels forever indebted for his care during her treatment, which consisted of cycles of radiation, high-powered radioactive beams administered to the cancerous body area, and chemotherapy, a combination of potent drugs. Both have potentially severe side effects including hair loss, nausea, fatigue, energy loss, weight loss and depression.

"He went to school at night so he could take me for radiation treatment every day," she recalls. "When I was on chemotherapy there were days when I would never get out of bed. We had a big calendar in the bathroom and he kept track of everything my body was doing and of the pills I had to take. I hardly talked to him; I just isolated myself. I was a pretty depressing person to live with."

Yet he recently told her, she says, that had he known she had cancer when he met her, he would not have pursued her friendship.

An expansion of his attitude is one that many cancer patients say they often encounter. Cancer, they contend, still holds a stigma similar to that of a contagious social disease. Bad enough on a social level, the stigma often permeates the work place.

In the Stanford study of Hodgkin's patients, 42 percent reported difficulties at work attributed to their cancer experience. Patients were not offered jobs, not promoted, demoted and denied benefits. Many feared the effects of telling employers about their disease. Perhaps most agonizing of all, patients reported being denied health and life insurance because they had cancer.

"I am completely uninsurable," Schleimer says. "If my company decides to drop me, no other insurance company will touch me. With each visit to the physician costing $175, and one hospital visit $12,000, you have no idea how stressful that is."

When his wife recently began looking for a new job, he says, a major consideration was the size of the company. The larger the company, their reasoning went, the better chance of good insurance coverage.

more

Cases of job discrimination have now started to surface throughout the country. A Philadelphia firefighter was rejected from the Coast Guard Reserve; a New York woman was rejected by the New York City Police Department. For the first time, the U.S. Congress is considering a proposal, introduced by New York Rep. Mario Biaggi, to amend the 1964 Civil Rights Act making it illegal to discriminate on the basis of race, age, sex, national origin or cancer history.

"We're trying to fill in a gap in the legal system to prevent discrimination against people with a history of cancer because most of the time it has no effect on their ability to perform a job," says Barbara Hoffman, a Philadelphia civil rights lawyer who presented the first draft of the proposal to Rep. Biaggi.

"We are just beginning to see this kind of problem," says psychiatrist Spiegel. "Health care plans are pressuring subscriber companies not to hire people who have had cancer in the name of cost containment. From an actuarial point of view it may make perfect sense but from a public policy point of view it stinks. When you combine this type of attitude with the improved survival rates, you realize that we haven't even begun to see how bad this is going to get."

But these problems, or any other difficulties cancer brings on, are surmountable, survivors say. Many, through support groups or personal efforts, strive to help others in the situations they've been through. "Cancer," Grabowski says incredulously, "was a really good experience for me." Having cherished the support the hospital staff members gave her during treatment, she moved from a surgical intensive care unit to one in which cancer patients are cared for. "I want to be able to tell patients that it's okay to feel awful, that they can live with being bald for a while or with radiation mapping marks all over their bodies because people will still accept them and they'll be all right."

And Taylor spent the summer visiting other organizations' support groups to get ideas on how to improve those offered by Stanford. "Life now is much more complicated," she says, "but that makes it a challenge. I have a lot of pride. Anyone who can face a challenge like cancer can do anything."

MOLECULAR SWITCH TURNS INACTIVE GENES INTO "WORKAHOLICS"

STANFORD—

Scientists at Stanford University Medical School and the Linus Pauling Institute in Palo Alto have isolated a small piece of DNA that can turn an idle gene into the genetic version of a "workaholic."

The finding could be valuable to the biotechnology industry and in scientific and medical research, the scientists believe.

The DNA fragment, called a promoter, is basically the "on-off" switch from one of the most active genes found in mammalian cells, explained Dr. Larry Kedes, Stanford professor of medicine who is based at the Palo Alto Veterans Administration Medical Center.

With genetic engineering methods, last year the researchers isolated and cloned the promoter fragment. More recently they have determined the sequence of its nucleotide subunits.

Using additional genetic engineering techniques, the scientists are now coupling the promoter to other genes, and they have successfully turned normally sluggish genes into hardworking ones.

"This promoter gives us a new approach to regulating gene expression in mammalian or human cells," said Dr. John Leavitt, head of the molecular carcinogenesis group at the Pauling Institute.

Kedes, Leavitt, Dr. Peter Gunning and their colleagues published reports on the promoter in the October issues of two scientific journals, the *Proceedings of the National Academy of Sciences* and *Molecular and Cellular Biology*.

Their research has been funded by the National Institutes of Health, the Veterans Administration, the National Cancer Institute, and the American Cancer Society.

Scientists have known for about a decade that stretches of DNA called promoters help determine gene activity levels inside cells. When a gene's promoter gives the green light, then cells express that gene by synthesizing the protein whose structure the gene directs.

But because some promoters are more powerful than others, not all genes are expressed at the same level. The promoter of one gene may tell a cell to make only a few copies of its protein while the promoter attached to another gene tells the cell to make thousands of copies of its product.

The promoter isolated by the Pauling Institute/Stanford team is set permanently to the "on" position. "This may be one of the most efficient promoters in nature," Leavitt said.

The promoter is very active because it drives the gene that codes for one of the most in-demand, abundant proteins in mammalian cells: beta-actin, the "brick" used throughout the cell's structural scaffolding.

Using recombinant DNA techniques, Gunning, a senior research associate in Kedes' lab, has designed a way to couple the promoter to genes other than beta-actin. Like a cassette machine that can play any tape that's plugged in, the beta-actin promoter then will direct high levels of protein expression for any gene to which it's attached.

"Since this promoter operates in many different kinds of mammalian cells, it could be widely useful in a large variety of cells in industry to boost production levels of biologically or commercially valuable proteins," Kedes said. "Any time you can improve a process by increasing the production per cell of the protein, there's an obvious benefit."

The promoter is expected to be effective only in mammalian cells rather than in bacteria, which are the current workhorses of the biotechnology industry. But as more companies tool mammalian cells into tiny protein factories, the promoter could become more important, he said.

An exciting, but speculative, potential use of the beta-actin promoter is in a new molecular approach to reversing cancer and other diseases, Leavitt said.

He and his colleagues will test the promoter's ability to squelch destructive genes by overpowering them.

The idea is to neutralize disease-related genes from viruses or bacteria, defective genes that govern genetic diseases, or genes associated with cancer, Leavitt explained.

The target is messenger RNA, a molecule that helps translate genetic information encoded in DNA into the language of proteins.

An RNA molecule can be neutralized by its complement, a second piece of RNA that fits into it like opposing strip of a zipper.

The scientists' strategy is to create a gene that produces that opposing RNA, which can then zip into the bad RNA from the disease-causing gene. "This has been tried in the past and has worked to some degree, but the process has never been efficient enough to make sufficient neutralizing RNA," Leavitt said. "You need to generate huge quantities to smother the target RNA."

That is where the extremely powerful beta-actin gene promoter comes in, Leavitt said. Harnessing it in front of a gene for disease-neutralizing RNA could be the key scientists need to make the experimental therapy work.

Other colleagues who worked with Leavitt, Kedes and Gunning include Drs. Ching-Shwun Lin, Sun-Yu Ng of the Pauling Institute; Drs. Roger Eddy and Thomas Shows of New York's Roswell Park Memorial Institute; and Dr. Phyllis Ponte of Stanford and the Palo Alto VA.

NEW TECHNOLOGY PERMITS PATIENTS TO ADMINISTER OWN PAINKILLERS

STANFORD—

Machines that allow hospitalized patients to administer their own painkillers have proven successful in three years of clinical trials at Stanford University Medical Center, says Dr. Paul White, an assistant professor of anesthesia.

White predicts the machines, called Patient Controlled Analgesia (PCA) devices, will be widely used within five years for cancer victims and surgical patients.

"Anyone who has undergone surgery knows how terrible it can be to be in excruciating pain and have to wait for a nurse to come with an injection," said White. "Then, it takes awhile for the painkilling drug to take effect. Subsequently, the patient may become groggy because a large dose of medication is required to produce a sustained effect. Then, the pain cycle starts again, and it might be awhile before their next injection."

With conventional nurse-administered analgesia, the usual time interval between injections is four hours.

The concept with the PCA machine is for the patient to administer small doses of painkiller as needed. The patient has by their bedside a button at the end of a cord, which is attached to the PCA machine. By pressing the button, a small amount of the analgesic is injected into an intravenous tubing that sends the pain reliever directly into the bloodstream.

A timer built into the computer-programmed machine inactivates the device for a period of from five to 15 minutes after the pain medication is administered to ensure that patients do not inadverently overmedicate themselves.

"Because the patient isn't as groggy as with nurse-administered injections," White said, "most surgical patients are able to get up and become mobile sooner using the PCA. Also, we've found that most patients use less medication with the PCA. And, because the patient is taking responsibility for their own care, there's a real psychological benefit."

White, who has a Ph.D. in Pharmacology as well as an M.D. degree, added that pain and anxiety are clearly interrelated. "Increased anxiety will make pain less tolerable," he said, "and conversely, increasing pain enhances anxiety.

"Highly aggressive patients consume more medication than patients whose coping styles are more passive. The PCA helps patients keep their anxiety in control because the pain never reaches a level that can be close to intolerable for some."

White said PCA machines have been used on about 250 post-surgical patients at Stanford over the last three years with great success.

The first research on the devices was done in this country about 15 years ago, but the PCA machines only became commercially available last year, he added. Each unit costs from $1,500 to $3,000, although some community hospitals are leasing machines for about $80 per month each, said White.

There are currently four commercially-available PCA devices for hospital use, the anesthesiologist said, and others are being developed for use both inside and outside the hospital environment.

"Although there are risks associated with the injection of any medication, including the narcotic analgesics given by nurses, the chances of serious injury or death from using the PCA are virtually non-existent if the machines are programmed properly and their use explained clearly to the patients," said White.

more

10-22-85

"In trials with about 250 patients, we've only had two minor problems resulting from the patients not clearly understanding how to use the PCA. Because the patients still are closely monitored by nurses, those problems were easily rectified," he continued.

White said one of the patients under-utilized the device because she had difficulty adjusting to the idea that she was responsible for administering the medication, rather than the nurse. He said the other patient developed transient hypotension (lowered blood pressure), which seemed to be the result of excessive use of the PCA device. Later it was learned that this patient had a history of drug abuse, and so the amount of medication the machine dispensed was lowered, and the patient was able to continue using the device without problems, the physician added.

"There were no cases of morphine overdoses requiring the use of opiate antagonists (counteracting medications)," said White.

He concluded that the vast majority of patients preferred PCA therapy to their previous postoperative analgesic regimes. However, one patient stated a preference for injected intramuscular medications "because she was more sleepy and therefore had less recall of the early postoperative period."

* * *

For writers interested in the types of PCA machines available, details follow:

The Abbott Life Care PCA Infuser (Abbott Laboratories, North Chicago, Ill.) combines microprocessor (with self-checking electronics) and stepping motor technology for the delivery of intermittent doses of medication from prepackaged, disposable cartridges. It is a lightweight (14.5 lbs.), portable, computerized infusion pump with a lockable security door that prohibits any unauthorized person from getting to the drug or the controls while the unit is in operation.

The Bard Harvard PCA Pump (C.R. Bard, Inc., Englewood, Colo.) is a portable syringe infusion pump capable of both continuous and intermittent infusion. The pump is a stepper motor which is microprocessor-controlled to prevent faulty operation due to an empty drug syringe, low flow, excess pressure, low battery, or control circuit failure.

The Intermedics (Graseby Dynamics) Cardiff Palliator (Intermedics Inc., Angelton, Tex.) is a line-powered syringe pump, which is pre-programmed to deliver the desired dosage of medication at a pre-determined flow rate. The parameters are adjustable over a wide range to accomodate a variety of drugs and dosage regimens. To minimize the possibility of the button being pressed accidently, the button must be pressed twice within one second to release the medication.

The Pharmacia Prominject Pump (Pharmacia Laboratories, Piscataway, N.J.) is a microprocessor-controlled, programmable infusion pump with three different modes of operation — patient-controlled, consecutive infusions, and constant infusion.

In addition, Pharmacia is marketing a small (15 oz.), portable, programmable infusion device (Deltec Cadd-Pac), which can provide for the delivery of pain-relieving medication outside the hospital environment.

HOW DEVELOPMENT OF A SYNTHETIC GROWTH HORMORE WILL AFFECT TREATMENT

STANFORD—

The Food and Drug Administration's approval of a genetically engineered human growth hormone has tremendous implications for medical treatment in general, but for 60 young patients at Stanford Medical Center, it has a more specific meaning: They can start receiving growth treatments again.

The 60 children had been receiving natural growth hormone extracted from the pituitary glands of human cadavers, but that treatment was stopped earlier this year because of indications it might be responsible for development of an extremely rare, always-fatal infection called Creutzfeld-Jakob disease. The virus of the disease can incubate for years before it appears. Experts estimate the risk of it occurring in people under 40 as only about 1 in 100 million.

Four deaths from Creutzfeld-Jakob disease were reported this year among young adults who had received the natural growth hormone. The first death reported was that of a 20-year-old man who was a patient of Dr. Raymond Hintz, professor of pediatrics at Stanford School of Medicine.

The discovery of four cases in a brief time, Hintz said, "makes it seem almost impossible that it was a matter of chance." However, he said, any determination of a link between the natural hormone and Creutzfeld-Jakob disease awaits the results of animal tests that will be released in about a year.

Although it is believed that any danger in the use of natural growth hormone was eliminated when refined methods of preparation were adopted in 1977, distribution of the hormone was halted earlier this year by the National Hormone and Pituitary Program.

That meant an anxious waiting period for children who are deficient in growth hormone and need treatment to avoid dwarfism. The hormone must be given before a child reaches puberty to be effective and some children nearing puberty have been particularly concerned about the cessation of treatments.

Hintz said all of the Stanford patients who were receiving the natural hormone before will be put on the synthetic hormone as quickly as possible, "we hope within a month."

He said Genentech Inc., the South San Francisco company that makes the hormone under the trade name Protropin, expects no problems in meeting all the needs although there could be a slight delay in getting it distributed to all the hospitals using growth hormone.

Stanford has been one of about 10 medical centers across the United States testing the synthetic growth hormone for the past four years. More than 200 children have been tested, Hintz said, and "the consensus is it's safe and effective."

Approval of the synthetic hormone should open the way to other research, Hintz said. He said he and Dr. Ron Rosenfeld, associate professor of pediatrics at Stanford, have been involved in research testing the effectiveness of growth hormone on 70 girls around the country suffering from Turner's syndrome, a chromosomal defect in females that causes stunted growth and other deformities.

"Other possible uses (for the hormone) are under research or will be fairly soon," he said.

Genentech officials said the synthetic hormone would cost $6,000 to $10,000 for a year's treatment, slightly less than the natural hormone. Hintz noted, however, that at least two other companies are testing synthetic growth hormone. "I think as soon as competition exists, the price is likely to drop," he said.

SMITHKLINE BECKMAN SCIENTIST DESCRIBES MALARIA VACCINE RESEARCH

STANFORD—

An anti-malaria vaccine, made through a new high-yield genetic engineering process, may be tested in U.S. Army volunteers next year, a research scientist said Thursday, Oct. 17 at a scientific symposium held at Stanford University Medical Center.

If effective, it could become one of the world's most widely used disease prevention agents because malaria, a parasitic disease spread by tropical mosquitoes, infects hundreds of millions of people worldwide.

The vaccine has nearly completed preclinical tests proving that it stimulates antibody production against the malaria parasite in mice and rabbits, reported Dr. Martin Rosenberg, vice president and director of the molecular genetics department at SmithKline Beckman, Inc.

Studies have also demonstrated that the test substance can block the parasite from invading human liver cells in the laboratory, Rosenberg said. Soon, Food and Drug Administration approval for human testing will be sought, he added.

Rosenberg spoke at a symposium on genes and disease organized by the Stanford Center for Molecular and Genetic Medicine and sponsored by Beckman Instruments, Inc., in celebration of the 50th anniversary of the company's founding.

The vaccine is being developed collaboratively by Dr. Wayne Hockmeyer and other scientists at the Walter Reed Army Institute of Research and the National Institutes of Health, with Rosenberg and his colleagues at SmithKline Beckman.

The agent blocks an early stage of the life cycle of the malaria parasite, *Plasmodium falciparum*, Rosenberg said.

Infection begins when the parasite slips into the body in the saliva of a biting *Anopheles* mosquito. Shortly after it enters the bloodstream, the tiny parasite—at this stage called a sporozoite—migrates into the liver where it matures into a different form and then multiplies in the red blood cells.

The vaccine is designed to snare the sporozoite before it can enter the liver, Rosenberg said.

The vaccine consists of protein material identical to portions of a protein that coats the surface of the sporozoite, he explained. The researchers hope that injections of the vaccine will stimulate a person's immune system to manufacture antibodies that recognize portions of the sporozoite protein.

Then, if the malaria parasite ever invades an immunized person, his body is already stocked with antibodies to attack and eliminate the sporozoite.

Rosenberg described how he, Dr. Jim Young, and other scientists at SmithKline Beckman employed genetically engineered bacteria to obtain high yields of the test vaccine.

They inserted a small piece of DNA into *Escherichia coli*, a bacterium widely used in the biotechnology industry. The DNA contained the gene that produces the sporozoite protein, isolated from the malaria parasite by scientists at NIH. The DNA also contained regulatory signals telling the bacterium how to interpret the foreign gene.

The scientists also engineered some special genetic tricks into the bacterium to obtain record harvests of the foreign protein, Rosenberg said.

One of these special adaptations prevented *E. coli* from destroying the foreign protein before it could be harvested.

The other enabled the scientists to grow a large number of the bacteria while keeping the foreign gene suppressed. By simply raising the temperature at which the bacteria were growing, the scientists could flick protein production on in the bacteria, which spewed out huge quantities of the product before dying.

Rosenberg said that in a little less than two hours, 10 liters of bacteria generated a quantity of protein equal to the amount that could be harvested from the parasites contained in a hundred million million (1 followed by 14 zeroes) mosquitoes.

AIDS APPEARED FIRST IN DRUG ADDICTS, EXPERT SAYS

STANFORD—

Drug abusers may have been among the first to come down with acquired immune deficiency syndrome (AIDS) in the United States, according to Dr. William Haseltine of the Dana Farber Cancer Institute at Harvard, who spoke at Stanford Thursday, October 17.

Haseltine said the presence of the virus among drug users has "worrisome consequences" for the general public, as many prostitutes are also addicts.

In central Africa, he said, a fourth of the men who report visiting prostitutes carry the AIDS virus, whereas of men who do not, only five percent have antibodies to the AIDS virus.

Haseltine cited the work of Dr. Don Des Jarlais who found that by 1979, when the first cases of AIDS appeared in homosexual men, intravenous drug users in Manhattan were also infected with the virus that causes the disease.

As doctors began to see damaged immunity in the gay population, Haseltine said, they noted another malady that was striking drug users. They were diagnosing a "walking pneumonia," in addicts whose congested lungs had "filled up" with white blood cells, he said.

The lung disorder, called lymphoid interstitial pneumonitis, is caused by the AIDS virus, and it is also common in children with AIDS, Haseltine said.

Blood samples collected from 40 drug abusers in 1979 were tested recently by Des Jarlais, a researcher with the New York State Division of Substance Abuse Services.

In a telephone interview Thursday, Des Jarlais said that blood from 13 of the 40 addicts contained antibodies to the virus that causes AIDS. Today, he estimates, 60 percent of the city's illicit drug users carry the virus in their blood.

Haseltine detailed his own research on the family of viruses that includes HTLV-III, the one that causes AIDS, in a talk at the Beckman Scientific Symposium on Genes and Disease at Stanford University School of Medicine.

10-18-85

more

He described how HTLV-III efficiently invades and takes over the metabolic machinery of human cells.

Retroviruses such as HTLV-III insert themselves into the nucleus of a host cell. The infected host cell now churns out viruses, in addition to its own products.

Unless this genetic merger takes place, Haseltine said, these viruses cannot reproduce themselves.

Like any other member of the retrovirus family, the AIDS virus sets out to be a "good parasite," he said. But in humans, HTLV-III is too successful an invader.

The AIDS virus has a unique gene that spurs the genetic controls of the host cell, so that it makes lots of virus, Haseltine said.

By rapid replication, the virus gains the advantage of quickly swelling in numbers, he said. But, he added, the disadvantage is that the host cell burns out and dies.

"Now that we understand this gene, we may be able to make drugs to counteract the (AIDS) infection," he said.

Because HTLV-III kills one of its host cells in humans—immune cells called T4 helpers—it causes the disease AIDS. But the virus also has more subtle effects in people that resemble more closely its probable origins as a parasite, Haseltine said.

It can ride into the brain within white blood cells "like a Trojan horse" and slowly destroy nerve cells, and it also causes the interstitial pneumonitis seen in drug addicts, he said.

These actions more resemble those of successful retroviruses which can co-exist with their host for years, he said, such as the visna virus that slowly kills sheep with lung and brain disease.

In contrast, he said, the rapidly lethal effects of HTLV-III on human T4 helpers make it a "maladapted virus for man."

JACOBS IS ACTING DERMATOLOGY CHAIRMAN; FARBER TO RETIRE

STANFORD—

Dr. Paul Jacobs has been named acting chairman of Stanford University School of Medicine's department of dermatology, succeeding Dr. Eugene M. Farber, professor and chairman who is retiring after 35 years at the post.

Jacobs, professor of clinical dermatology, has served on the Stanford faculty since 1970 after a number of years of practice in military medicine and as a member of the faculty of Georgetown University Medical School. He is a graduate of the Stritch School of Medicine, Loyola University in Chicago.

The appointment was announced by Dr. David Korn, dean of the School of Medicine. Korn stated that he had granted Dr. Farber's request for a sabbatical leave starting Oct. 1, 1985, for the remainder of the current academic year, with his retirement to be effective Sept. 1, 1986.

"Dr. Farber has informed me that the exigencies of his health necessitate his relinquishing his university and hospital positions and duties," said Korn. "We are grateful for his many contributions to the university, and wish him well in his retirement."

Farber recently told the Stanford University News Service that the need to end his university activities was influenced also by the time and energy required to defend against charges filed in Jan. 1985, by a former female patient seen by him at the university dermatology clinic. Farber pleaded innocent in Palo Alto Municipal Court in Jan. 1985. No hearings have occurred to date.

Farber's attorney, Harry B. Bremond, said, "We are certain that he will be vindicated; the charges are entirely without foundation. We believe the university's internal proceedings would also have exonerated our client."

A university investigation was begun in Jan. 1985, but was delayed for months while first-hand testimony was not available to the university. The investigation was governed by faculty disciplinary procedures, which require it to remain confidential.

Korn stated that the proceedings were not completed, and have been made moot since Dr. Farber no longer has any institutional duties.

Joining the Stanford faculty from the Mayo Clinic in 1948, Farber was appointed dermatology chairman in 1959 when the School of Medicine was moved from San Francisco to the campus.

Among Farber's contributions are the training of more than 200 specialists in dermatology, the development of the nation's first Psoriasis Day Care Center, and research to obtain basic knowledge about the biology of the skin.

SCIENTIFIC ADVANCES HELP DEVELOPMENT OF NEW WHOOPING COUGH VACCINE

STANFORD—

Stanford University scientists are helping to develop a new generation of whooping cough vaccines that may be safer than the current injection, whose rare side effects have raised a controversy over its compulsory use.

The scientists have identified a toxic component of whooping cough vaccine that is responsible for seizures or convulsions in an estimated one of every 750 vaccinated children and permanent brain damage in one out of 300,000. They also have cloned the harmful toxin's gene from the bacterial agent that causes whooping cough.

These advances are helping to speed the development of several alternative forms of a vaccine to prevent whooping cough.

On one front, the scientists are already testing in mice a vaccine that lacks the harmful component. On another front, they are using genetic engineering techniques to manipulate the offending bacterial gene so as to chemically defuse its toxic effect. The weakened gene could then be replaced in the whooping cough organism to provide another possibly safer vaccine.

The research is taking place in the laboratories of Dr. Stanley Falkow, professor and chairman of medical microbiology at Stanford, and Dr. Lawrence Steinman, associate professor of neurology.

Falkow will report on the progress Thursday (Oct. 17) at a scientific symposium to be held at Stanford Medical Center to celebrate the 50th anniversary of the founding of Beckman Instruments, Inc. In addition, some of the findings soon will be published.

Whooping cough, sometimes called pertussis, is a respiratory illness that annually in the U.S. infected hundreds of thousands—and killed thousands—before the vaccine became available about 40 years ago. (It is still a killer in many underdeveloped parts of the world, Steinman said.)

The current whooping cough vaccine is made from the bacterium that causes the disease—*Bordetella pertussis*—and is administered to infants and children in "DPT" shots which also include vaccines against diphtheria and tetanus.

Controversy over its use has boiled up in the last several years. Two of the drug's three major manufacturers halted production last year, citing increasing costs associated with insurance and with lawsuits by families of brain-damaged children. As a result, some parents, frightened by the vaccine's rare side effects, have refused to get their children immunized.

Most physicians feel that protection against the disease far outweighs the small risk of side effects, said Steinman, a pediatric neurologist. But even though the risk of nervous system damage is small, the vaccine could be improved, he added.

Steinman, Falkow, and their colleagues recently identified pertussis toxin, one of several chemicals the whooping cough microbe produces, as the culprit that causes the adverse reactions.

more

They made a test vaccine from a *Bordetella* strain modified to produce a defective pertussis toxin. When administered to specially bred mice that are highly susceptible to the standard vaccine's side effects, the modified vaccine was 100 times weaker in its ability to cause neurological damage, Steinman said.

And although no other purified protein from the normal whooping cough bacterium produces neurologic damage when injected into the inbred mice, shots of purified pertussis toxin cause nervous system effects resembling those seen in affected children.

These findings suggest that the *Bordetella* strain with defective pertussis toxin might be a good candidate for a safer human vaccine, Steinman said. Preliminary studies suggest that mice given the vaccine develop a protective immune response against the bacteria, and this may prevent the disease, he noted.

Other promising vaccine candidates are being developed by researchers in Falkow's laboratory who have isolated and cloned the gene that codes for pertussis toxin. They are trying to develop new strains of the organism that are crippled in their ability to cause side effects but retain the ability to trigger a protective immune response.

With gene splicing techniques, Dr. William Black, a postdoctoral fellow in Falkow's lab, cut up the pertussis toxin gene into pieces. Inserting single pieces of the gene back into a whooping cough bacterium then creates an organism that makes defective pertussis toxin. Since the small gene pieces cannot make the entire pertussis toxin protein, side effects should be minimized. But even small pieces of the gene may produce enough of the protein to elicit a protective immune response against the disease, Falkow explained.

But although Steinman said his group is just "half a step away from saying we have a good vaccine candidate for human testing," scientists face a statistical dilemma in actually demonstrating a new vaccine's improved safety.

Statistical rules would require a clinical trial of nearly one million children to prove the new vaccine's safety is better than the current vaccine's one in 300,000 odds, he said. "Other than our experience with polio and swine flu, you don't usually start clinical trials of that size," he remarked.

"But nobody likes to see a child have a convulsion," he added. Even a smaller clinical trial that could demonstrate improved safety above the one in 750 odds of seizures would be a "significant improvement," Steinman said.

The researchers also are working on ways of predicting which individuals might be at greatest risk for developing adverse reactions from the current vaccine. In mice, they have found that the strains most susceptible to the vaccine's side effects share a genetic factor that controls their immune response to bovine serum albumin, a protein found in cow's milk. Steinman said that further research may show if a similar genetic predisposition exists in people.

Others who were involved in the research are Drs. Alison Weiss and Erik Hewlett, now at the University of Virginia, Drs. Scott Stibitz and Nancy Adelman, Mae Lim, Richard Zuniga, and John Oehlert, all of Stanford.

The research funding came from the National Institutes of Health.

CO-FOUNDER OF WINNING PEACE GROUP ASTONISHED AT GROWTH

STANFORD—

The awarding of the Nobel Peace Prize to the International Physicians for the Prevention of Nuclear War (IPPNW) prompted feelings of "great joy" and "some astonishment" in Dr. Herbert Abrams, professor of radiology at Stanford University Medical School.

The joy was a natural reaction to the recognition for an organization he helped found. The astonishment was at "the degree to which in five years the organization has been able to reach goals that we defined for it at the outset."

It was actually a little more than six years ago—in June, 1979—when a few members of the American organization Physicians for Social Responsibility met to consider the possibility of forming an organization of physicians from many countries.

Abrams, at the time chairman of the department of radiology at Harvard Medical School, became vice president of the embryonic organization. Dr. Bernard Lown, a Harvard cardiologist, became president, and Dr. James Muller, also a Harvard cardiologist, was named secretary.

Later that year, Lown and Dr. Eugene Chazov, personal physician to Leonid Brezhnev, exchanged letters on the role physicians could play in reducing the threat of the accelerating nuclear arms race. It wasn't until October, 1980, however that the IPPNW really got started at a formative meeting of American and Soviet physicians in Geneva.

Once started, it grew rapidly. There are 30,000 members in the United States and more than 100,000 in 58 other nations. The Soviet Union, Abrams says, claims to have one million members of IPPNW.

Abrams left Harvard in 1984 to return to Stanford, where he had been director of the diagnostic radiology division from 1960-67 and an instructor and professor in radiology from 1951-67.

In the past year, his concentration on anti-war activities has led him to scale down the medical research that earned him international recognition in the field of cardiovascular radiology. He is the author of the first definitive text on angiography as well as several other books and more than 150 articles.

He is a member in residence of the Center for International Security and Arms Control at Stanford, and has a heavy writing and lecturing schedule for that organization that parallels his work for the IPPNW.

Despite the distance from the IPPNW headquarters in Boston, he has maintained a very active role in the organization. He is a member of the IPPNW advisory committee and he writes and lectures extensively on the nuclear threat. He has addressed large audiences in Moscow and Leningrad and appeared on Soviet television.

In recent years, Abrams has become particularly involved in writing and lecturing about the dangers of accidental or inadvertent nuclear war. In September, he prepared a 65-page pager on "Sources of Human Instability in the Handling of Nuclear Weapons" that cataloged the human weaknesses in military personnel involved in the handling of nuclear weapons. The paper was delivered at a symposium on the "Medical Implications of Nuclear War" sponsored jointly by The Institute of Medicine and the National Academy of Science.

The role of physicians in saving life makes it natural for them to be involved in the anti-nuclear movement, Abrams says. Since medicine has no national boundaries, he points out, it's easy for physicians from many nations to work together on political issues as they have in IPPNW.

IPPNW has formed "a bridge between East and West," Abrams said, emphasizing that American and Soviet physicians have made a determined effort to "depoliticize" their role in preventing nuclear devastation.

He scoffed at critics who object to Americans working with Soviet physicians, saying he welcomes their participation "if they can help in accomplishing the goals of making the world alert to the dangers in nuclear weapons."

Winning the Nobel prize is almost certain to make IPPNW more effective in delivering its message to world policy makers, Abrams said. He said he is among American members of the organization who plan to make personal calls on President Reagan stressing the importance of arms-control talks in Geneva.

(EDITORS: photos available if not included.) **HOW TO DEAL WITH CHRONIC PAIN**

STANFORD—

When clinical psychologist JoAnn LeMaistre conceived of the idea for her new book, "Beyond Rage: The Emotional Impact of Chronic Physical Illness," she had no idea she'd be writing about her own experience.

Now that the book, which defines the six stages of emotional response to chronic physical illness, is published, LeMaistre realizes it was as therapeutic for her to write as she hopes it will be for all who read it.

The message LeMaistre strives to convey in her book is that the emotional responses chronically ill patients may experience are normal. Eventually, she wants readers to know, they will feel psychologically better.

"I want people to realize that there are very competent people who are walking around with very serious illnesses," she says. "They need to learn to see the competence and not just the illness."

LeMaistre is a victim of multiple sclerosis, an incurable progressive deterioration of the nervous system. The disease first surfaced about seven years ago, within a month of completing her post-doctoral training at Stanford University Medical Center, completing her dissertation and giving birth to her daughter.

"My neurologist said he had never seen such a malevolent force," she recalls.

It took her nearly two years to adapt to her new physical limitations, which include being legally blind and having lost control of many muscular functions. During that time she studied and passed the licensing exam required of all working psychologists. She also had to regain the professional and personal confidence the disease wiped out in order to be able to continue seeing patients and caring for her daughter, for example.

Today LeMaistre is victorious. She has a busy private practice, in which she specializes in the care of the chronically ill. She teaches in the psychiatry and behavioral sciences department at Stanford. She advises psychology interns. She provides inservice training for other health care professionals. She gives lectures to professional and community groups. In 1982 she received the Mother of the Year Award from the Santa Clara County Multiple Sclerosis Society, and in 1984 LeMaistre received the Distinguished Humanitarian Contribution Award from the California State Psychological Association.

The original concept for the book came to LeMaistre while she was working as an intern at Stanford University Medical Center's Pain Clinic. She conducted the psychological testing of patients, whose data showed her that when people did not physically feel well, they experienced "massive psychological changes, such as depression and anxiety, as well."

"I never expected that I would be almost two years recovering from an unexpected illness that completely laid me out," she says in her articulate and softspoken manner. "But it did give me a lot of time to think about this book."

LeMaistre describes the six stages of chronic illness through anecdotes and analysis. She attempts to make readers aware of harmful and destructive responses, and tells how to avoid or eliminate them. She stresses positive responses, which she hopes serve as a guide to patients, families and physicians.

The six stages include*crisis*, during which time the patient is afflicted by the illness; *isolation*, a common reaction when the patient realizes the illness is not going to go away; *anger*, the reaction to the realization during the isolation stage; *reconstruction*, the patient's attempt to try to adapt to a new lifestyle; *intermittent depression*, periods when a patient may go through setbacks in spite of being determined to return to as productive a life as possible; and finally, *renewal*, a patient's self-acceptance of a new physical and psychological state.

"Other books of this type have been geared towards the care taker," LeMaistre says. "This one is geared toward the patients, their families and friends. Physicians are telling me that when they lend the book to a patient, it ends up being passed around and read by many people.

"Someone recently told me that after reading the first chapter he spent an hour crying because it was the only thing he'd ever read that hit all the right chords.

"*Beyond Rage* seems to be having just the effect I was hoping it would," she says.

REPORT QUESTIONS CATHETER USE IN PATIENTS WITH HEART OR LUNG DISEASE

STANFORD—

The use of Swan-Ganz catheters in patients with lung or heart disease has increased dramatically in recent years despite evidence that the risks of the procedure exceed benefits, a Stanford University professor said Wednesday, Oct. 16.

The catheter, a balloon-tipped hollow tube floated into the blood vessels of the lung, is commonly used in hospital intensive care units to measure the pressure in these blood vessels. The procedure differs from the ordinary cardiac catheterization used to diagnose narrowing of coronary arteries. Swan-Ganz catheters are left in place for monitoring patients over substantial periods of time.

"But it has become clear," wrote Dr. Eugene D. Robin, "that improved outcome is found only in small groups of patients and that use of these catheters is associated with considerable complications, including death."

Robin, a professor of medicine and physiology, said there is a need for well-designed clinical trials to evaluate the catheter and its use which has reached "epidemic proportions."

"While awaiting such trials," he said, "physicians should limit catheter use to patients on whom there is a large probability that measurements can answer specific questions about therapy." The number of such patients would be very small, he added.

Robin's remarks appear in an article in the September issue of the *Annals of Internal Medicine* in which he reviews recent studies on the catheter's use. The work was supported in part by a grant from the Samuel and Leah Osher Medical Education Fund.

One such study provides direct evidence of a high level of use of the catheter in critically ill patients, Robin wrote. In the study, which involved close scrutiny of 142 consecutive postmortem examinations, 55 (38 percent) of the patients had undergone pulmonary artery catheterization before death.

"In the absence of data derived from an acceptable clinical trial," said Robin, "it is not possible to determine which of these patients were catheterized 'appropriately' or 'inappropriately.' The point is that high frequency of use should be reserved for measurements unequivocally shown to have highly favorable risk-benefit ratios.

"If we assume that the patients who underwent postmortem examinations were typical of patients who died at that hospital, the data would indicate that almost 4 of every 10 patients are catheterized during the period of dying.

"These data, if generally representative of practice in American hospitals, would establish the use of the catheter as not only a rite but very commonly a last rite."

Robin cited indirect evidence showing extensive use of the catheter. Courses on intensive care for doctors in practice deal with its use, he wrote. Most intensive care and coronary care units training interns, residents and medical students provide similar instruction. And community hospitals hiring physicians for their intensive care units require that applicants know how to use it.

In some coronary care units, patients suspected of having suffered a heart attack have the catheter installed routinely when they are hospitalized, Robin said. This leads to the possibility that patients with essentially benign disorders like chest wall pain or viral infection of the percardium may undergo catheterization unnecessarily.

"Studies show the rate of complications from use of the catheter to be substantially high," Robin said. One study of critically ill patients with excessive fluid in the lungs, caused either by heart disease or other factors, showed that over 4 percent died of complications related to the Swan-Ganz catheter and between 20 and 30 percent of them had major complications requiring treatment.

Complications may range from blood clots and knotting of the catheter to heart arrhythmias and infections, Robin said.

The benefits of the catheter's use are difficult to define, Robin said, because often its measurements and subsequent interpretation are unsatisfactory and do not result in a significant change in the management of the patient.

"The results mislead rather than enlighten the physician," he noted.

There are major economic advantages resulting from use of the catheter, Robin wrote. "The fee paid to physicians for inserting the catheter is usually in the hundreds of dollars. An entire industry has been spawned in manufacturing and distributing catheters, as well as for the required recording equipment."

Robin said physicians not directly involved in critical care must act as advocates for the patients. They must ask how the catheter's use will benefit their patients. "If the expert cannot provide convincing answers, the physician must decline to have the device used on his patient," he said.

Some people have argued that catheter use leads to the accumulation of physiological data, Robin said. They assume that more data lead to better management of the patient.

"This result has not been shown," Robin said. "Even if there were no hazards or expense, these benefits might be acceptable. However, there are hazards and there is expense, and routine use of catheters to reap such benefits should not be acceptable."

Robin cited a Stanford University Hospital study showing that treatment of critically ill patients without pulmonary flow catheters is possible. The study involved 23 heart-lung transplant patients. A catheter was used in only one patient, despite the fact that many patients develop pulmonary edema (fluid in the lungs) following transplant surgery. The mortality rate in heart-lung transplant patients has been 20 percent compared to a 50 percent rate shown in patients with adult respiratory distress syndrome in whom the catheter is used routinely.

"Heart-lung transplant patients may be so special that general conclusions about the study cannot be drawn," Robin said. "Nevertheless, the data provide a challenge to advocates of catheterization."

FEWER PATIENTS RAISE CONCERNS FOR STANFORD HOSPITAL

STANFORD—

Low patient census, finance, and ways to expedite applications of physicians seeking access to hospital laboratories preoccupied the October meeting of Stanford University Hospital's board of directors.

Sheldon S. King, executive vice president and hospital director, reported that the hospital is only 66 percent full.

"We may be seeing a reflection of what every other hospital is seeing, but it's an issue of great concern," he said.

The census has dropped by 2,000 patient days since last year, King said, and this will require further cost reductions while the hospital gets ready to implement new programs designed to bring the census back up. This cannot be achieved overnight, however.

Last year, the hospital through cost management achieved an $8.1 million reduction in expenses as part of a three-year $20 million goal. It has launched two new programs and has signed contracts with prudent buyer plans in an effort to maintain its share of the patient care market. But other area hospitals, the directors were told, are involved in more aggressive efforts while Stanford hospital, being part of a university with several missions, is often too slow in acting to stay ahead of its competitors. The reason: it is not simple to achieve consensus among various constituencies on the best and most appropriate way to proceed, the board was told.

Even with a lower census, however, reported Stanford Vice President for Business and Finance William Massy, the hospital continues to maintain a favorable financial condition—due mainly to the acuity of cases being treated. However, future uncertainties should be of concern to the board, he warned.

In other business, the board said that service access committees should shorten the timetable for acting on applications of community physicians seeking staff privileges in hospital laboratories.

While in general access policies are working smoothly, there have been some delays, explained hospital chief of staff James Silverman, because some physicians previously granted access do not utilize the facilities. The committee wanted to evaluate the pending requests around the applicants' plans to bring patients to the hospital. The committee was concerned about granting privileges to inactive physicians who keep other applicants out."

Hospital policies call for a specified number of slots available to community physicians in the specialized laboratories directed by full-time faculty.

The board suggested that its concerns be conveyed to the service access committees. And Stanford university president and hospital board chairman Donald Kennedy summed up the board's feelings. "While faculty members understandably are worried about those matters, the board is equally concerned about the hospital census."

In other action, the board voted to create an academic committee to advise the directors on issues affecting the hospital's academic missions.

10-16-85

more

The committee is expected to "facilitate and to support the synergy of the educational, research and patient care missions of Stanford University, the Stanford University School of Medicine and the Stanford University Clinic," the board stated.

The committee's role "will be important," said Kennedy, "in view of the changing relationships of the hospital and medical school."

Under the revised organizational structure, as Kennedy explained in a recent memo, the university and the hospital are sister "corporations"—separate entities with related goals and a common set of "owners," the Stanford's trustees who also serve as members of the hospital corporation. The university depends on the hospital to provide vital academic support for the missions of the medical school. In addition, the hospital is located on the campus. The actions of each affect the other in important ways. The hospital also serves as a community hospital for patients of physicians in private practice.

The committee, whose membership will be appointed shortly, will have at least five voting board members, including the dean of the School of Medicine and the board representative of the full-time faculty, and up to three voting non-board members, with the hospital board chairman and hospital president serving ex-officio.

Among its functions, the committee will advise the board on policies and plans that may influence the academic mission of the hospital, including medical student, graduate and postgraduate education and training.

The board approved in concept the hospital's strategic plan, a document which outlines approaches to keep the institution viable in a shrinking and highly competitive health care market.

The board also received a progress report on the hospital modernization project which is proceeding on schedule.

POSITIVE AIDS TEST REVERSED IN WOMAN EXPOSED TO VIRUS

STANFORD—

A woman who had tested positive for antibody to the AIDS virus and showed decreased immune cells has regained normal readings without contracting the disease, although only time will tell if she remains free of AIDS, Stanford doctors report.

Her case suggests that the decrease in immune cells caused by the initial infection with the AIDS virus may not always be irreversible, the researchers write in the October issue of *Annals of Internal Medicine*.

The findings show that at least one person who developed antibodies to the AIDS virus has lost her antibody response to it while remaining well, said Dr. William Robinson, professor of infectious diseases and principle author of the report.

"We will have to follow her for a long time to be sure of this," he cautioned.

In contrast to the woman in the report, those who become ill with AIDS lose their antibodies to the virus because their damaged immune system can no longer make them.

Robinson cautioned that the results should not be interpreted to mean the woman has recovered from AIDS, as she has never been ill with the disease as some press reports have suggested.

The woman was exposed to the virus through sexual relations with her husband, a hemophiliac who died of AIDS a year ago. He had probably acquired AIDS from contaminated blood products, the scientists wrote.

Although this is a single instance where the human body has recovered from contact with the AIDS virus, the case "suggests that avoidance of repeated exposure to LAV (the AIDS virus)...may sometimes result in recovery" of normal immune function and loss of antibody to the virus that causes AIDS, the scientists wrote.

The couple was referred to Robinson as subjects for his clinical research on the AIDS virus, he said.

Initial blood tests revealed that AIDS virus had entered the wife's body. But subsequently, after the couple began to use a condom during sex, antibodies to the virus disappeared from her blood, and she recovered normal numbers of disease-fighting cells, the doctors reported.

The couple's two children did not develop AIDS antibodies, they retained normal numbers of immune cells, and they have not had any sign of the disease, according to the report.

Neither the husband nor the wife admitted to intravenous drug use or sexual contact with any other partners, the report said.

Other authors of the report are Drs. Edgar Engleman and Jeffrey Lifson of Stanford University Medical Center; Drs. Harold Burger and Barbara Weiser, formerly of Stanford and now at the State University of New York at Stony Brook; and Dr. Luc Montagnier and associates at the Pasteur Institute in France.

The couple had continued to have sex after the husband developed the swollen lymph nodes, fatigue, and weight loss that often precede AIDS.

In December of 1983, the husband's blood had antibody to the AIDS virus, and he had a "severely decreased" number of T helper lymphocytes, the cells that are invaded and then killed by the AIDS virus.

In January of 1984, his wife was tested, and her blood also had the antibodies, and showed "mildly decreased" numbers of T helper cells, the report said.

In February, they started using condoms, and in March, the husband developed AIDS (specifically, an infection with *Pneumocystis carinii* pneumonia), and sexual relations stopped, the scientists reported.

He died in September, 1984.

When the wife was tested again in April, 1984 the antibodies were gone from her blood and the number of her T helper cells had reached normal values.

The husband's four brothers, sister, and mother were all well and had no evidence of AIDS antibodies as of April, 1984, according to the report.

MICROBUBBLES MAY REPLACE CATHETERIZATION

STANFORD—

Stanford University Medical Center scientists are testing special "microbubbles" as a new noninvasive method to detect high blood pressure in the lungs.

Preliminary results, reported in the October issue of California Medical Association's *Western Journal of Medicine*, show the experimental technique to be less risky, less uncomfortable and less expensive than the current method of catheterization.

More work, including developing a way to mass produce the carbon dioxide bubbles, is necessary before the technique is ready to test in humans, the researchers said.

The technique works by injecting the bubbles into a patient's veins. When they reach the heart, they vibrate at a frequency dependent on the surrounding pressure. The vibrations can be picked up by a microphone placed on the chest.

"This is just one of many ways being investigated as a way to avoid catheterization," said one of the article's nine authors, Dr. Stephen Oesterle, physician specialist in the departments of medicine and cardiology.

High blood pressure in the lungs, caused by stress, fatique and heart problems, can be fatal by causing one of the heart's arteries to rupture.

The current detection method of catheterization involves threading a long narrow tube from a leg artery to the heart. Because of its potential complications, such as infection, physicians are looking for alternative techniques, Oesterle said.

STANFORD SCIENTISTS FIND A BACTERIAL "INVASION" GENE

STANFORD—

Stanford University scientists have found a gene that allows disease-causing bacteria to invade animal cells.

The discovery—the first identification of a specific genetic factor required for the bacterial invasion process—should help scientists better understand the critical yet mysterious first steps involved in many bacterial infections.

It should also help advance the quest for new ways to stymie pathogenic (disease-causing) bacteria, which are becoming inreasingly resistant to antibiotics.

The invasion gene was found in a bacterium called *Yersinia pseudotuberculosis* by Drs. Ralph Isberg and Stanley Falkow, two Stanford medical microbiologists who reported the work in the September 19 issue of *Nature*.

Falkow, head of Stanford Medical School's department of medical microbiology, also will describe the research at a scientific symposium on genes and disease to be held in Stanford Medical Center on Thursday (Oct. 17) in celebration of the 50th anniversary of the founding of Beckman Instruments, Inc.

Although *Yersinia pseudotuberculosis* is not a major cause of human disease, it is closely related to the microbe that causes bubonic plague and it is responsible for a serious veterinary infection nicknamed "guinea pig plague."

It is one of a large class of bacteria—including the organisms that cause typhoid and tuberculosis—that infect by penetrating and surviving inside animal cells rather than growing outside cells, Isberg said.

Having identified the invasion gene, the scientists are now beginning to dissect the process by which bacteria penetrate cells in more detail, they said.

"The more we learn about pathogenic bacteria, the more able we are to combat their ability to grow," Isberg explained. "We're looking toward the day when we can use alternatives to antibiotics in fighting bacterial infections.

"If we can gain knowledge about particular steps in bacterial growth, such as invasion, then we may be able to design therapies that will block those steps without involving antibiotics," he added.

Another potentially valuable outgrowth of the discovery is that bacteria engineered to contain the invasion gene might become useful ferries for shipping substances such as drugs, other proteins, or even pieces of DNA, into animal or human cells, Isberg said. These ferries could be useful in medical therapy as well as in basic research.

Far more speculative but also a possibility, Isberg added, was the potential that the invasion gene could aid vaccine development by transporting weakened bacteria into cells, where they could persist long enough for the body to mount an immune defense against them.

The scientists found the gene using recombinant DNA techniques in which they transferred pieces of the *Yersinia* chromosome into *Escherichia coli* bacteria that cannot normally penetrate animal cells. Acquisition of the single gene turned the non-invading *E. coli* into bacteria capable of infiltrating animal cells grown in tissue culture.

In continuing studies, the researchers have found that the *Yersinia* invasion gene codes for a large protein found on the bacterial surface, Isberg said. But the researchers don't yet know whether that protein facilitates binding to the animal cell or whether it performs other roles that could be involved in invasion.

Isberg said the scientists were surprised to find that in *Yersinia*, a single gene confers the capacity to invade. But he added that as researchers investigate other bacteria that evolved separately, they may find variations in the invasion process requiring more, or different, genetic factors.

The research was funded by grants from the Jane Coffin Childs Fund for Medical Research, the National Science Foundation, and the U.S. Army Medical Research and Development Command.

UCSD RESEARCHER TO GIVE FIRST FEIGEN MEMORIAL LECTURE

STANFORD—

The first George A. Feigen Memorial Lecture will be held Friday, October 25 at 4:30 p.m. in Fairchild Auditorium.

The speaker will be Dr. Seymour Jonathan Singer, professor in the biology department of the University of California at San Diego.

His talk, entitled "The cell biology of cytotoxicity," will be followed by a reception and is open to all interested members of the community.

Originally trained as a chemist, Singer has made major contributions to variety of fields of biological research. He was the first to propose the fluid mosaic structure of cell membranes, a major leap toward the present understanding of how biological membranes function.

Singer also has been an innovator in studies of the structure of biological molecules, particularly those involved in immunological reactions, and with colleagues, he helped usher in the new era of molecular disease.

Feigen was a Stanford faculty member in the department of physiology from 1949 until the time of his sudden death in 1983. He was an authority on anaphylaxis and the mechanisms involved in its expression, and was widely regarded as an impeccable scholar and a first rate teacher.

The Feigen Memorial Lecture, established shortly following his death, is intended to bring distinguished immunologists to Stanford each year as a reminder of Feigen's numerous contributions to Stanford and to his many friends, students and colleagues.

CHILDRENS HOSPITAL AT STANFORD OPENS NEW CHILD PSYCHIATRY CLINICS

STANFORD—

The child psychiatry division at Children's Hospital at Stanford has added four new clinics to round out its clinical services, announced Dr. Herbert Leiderman, psychiatry professor.

"With the new clinics we can now provide more comprehensive and specialized services to our patients," said Leiderman, who directs the outpatient services.

"We have established a clear focus on family in treating children," he continued. "We want to help children in their home, school and play environments, and not simply treat them in isolation."

The new outpatient clinics include:

- a child and adolescent psychiatry clinic and an infant and preschool psychiatry clinic, through which a staff of psychiatrists, social workers and psychologists offers comprehensive assessment and therapy of infants, children, adolescents and their families;
- a pervasive developmental disorders clinic, through which staff members can treat developmental disorders such as autism;
- an obesity clinic, through which staff members can assess and treat children and adolescents for obesity, which "aside from the physical effects is known to have severe social consequences in this society as well," Leiderman said; and
- a medication clinic, through which staff members can consult and manage medication for children. "The responsible use of psychopharmaceutical agents is a relatively new area in child psychiatry," Leiderman said. "Many physicians and patients are not well acquainted nor feel comfortable with them."

The child psychiatry division has also established a consultation network for physicians in the areas of general pediatrics, birth defects and neurology.

The new clinics add to the existing outpatient services, which include specialized clinics in affective disorders, such as depression; gifted children; and eating disorders, such as bulimia and anorexia nervosa. Inpatient services are also available.

For more information call Leiderman at (415) 497-0817.

FOR IMMEDIATE RELEASE

STANFORD--One of the founders of the organization which Friday (Sept. 11) won the Nobel Peace Prize says the award validates the importance of recognizing the threat of nuclear war.

Dr. Herbert L. Abrams, professor of radiology at Stanford University Medical School, was one of the three American physicians who founded the prize-winning International Physicians for the Prevention of Nuclear War.

Abrams, Bernard Lamb and James Muller were all professors at Harvard Medical School when they formed the organization and began corresponding with Soviet physicians.

The Soviets were skeptical at first, but eventually agreed to the meeting in Geneva at which the organization was formed, Abrams said. The IPPNW now has members in 60 countries.

Abrams, who is now on the IPPNW's Advisory Committee, called the Nobel award ``very exciting recognition of the work the IPPNW has done in educating physicians, the public and policy makers on the very great threat of nuclear war.''

Physicians are a natural group to form such an organization because ``medicine has no national boundaries,'' Abrams said.

Abrams was at Stanford from 1951-67, as an instructor and professor in radiology. He was director of the diagnostic radiology division from 1960-67.

He went to Harvard in 1967, returned to Stanford as a visiting professor of radiology in 1980-81, and joined the Stanford faculty again as a professor of radiology on Sept. 1, 1984.

Nobel prizes are usually given to individuals, but news accounts have said that the peace prize has been given to organizations previously.

FOR IMMEDIATE RELEASE

STATUS OF RESEARCH ON AIDS

(Editors and Writers: Roberta Friedman is spending a year at Stanford University as an intern-fellow of the Council for the Advancement of Science Writing. The following article, based on published reports and interviews with scientists around the country, describes how science and medicine are tackling the disease.)

STANFORD—

For the past four years, two groups of scientists have been following parallel paths, both with their sights on the puzzle of AIDS, the disease which has lethally compromised the immune systems of 13,000 Americans.

While the discovery of the AIDS virus (HTLV-III) by basic scientists sits in the scientific spotlight, clinicians have been observing the disease in patients, tracking how it spreads and recording the results of experimental treatments. From such diverse activities and perspectives, scientists believe, a way to control AIDS will be found.

"I'm a virologist," says Stanford's Dr. William Robinson, "so I think of all the viruses I know, and test ideas I have learned from them."

An expert on hepatitis B, he points out parallels between that blood-borne disease and AIDS. And he focuses on becoming familiar with the habits of HTLV-III, the better to outwit it.

A different tack is taken by Dr. Edgar Engleman, a Stanford immunologist. To him, the AIDS virus has been a jigsaw piece that fits neatly into his own research puzzle—finding the function of a molecule that sits on the surface of immune cells called T4 helpers.

T4 helper cells happen to be the ones killed by the AIDS virus.

Engleman had just shown that one of the cells' receptor molecules, named CD4, is critical to the proper performance of T4 helpers, when, he says, "lo and behold, here comes this virus that appears to use this molecule to attach to the cell and get in."

He is now investigating just how the AIDS virus latches onto, invades, and ultimately destroys these front-line defenders of the body's immune system. Describing the virus's invasion mechanism, Engleman says, could suggest a design for a drug to jam it.

Still another question some scientists ask is, did the AIDS virus cross the species barrier from animals to man? These researchers hope that learning about animal versions of the virus will lead to a vaccine as successful as the one against smallpox, which Edward Jenner crafted from the cowpox virus, vaccinia, in the 1800s.

"Jenner used the fact that certain viruses penetrate the species barrier to point the direction to control diseases in man," explains Dr. Thomas Merigan, chief of infectious diseases at Stanford.

"Through Jenner's approach, smallpox has become the only infectious disease we have controlled on a world-wide basis," he adds.

In the case of cowpox virus, the new host, humans, are not harmed, and are protected against smallpox. Other instances of cross species spread, Merigan says, do not give such happy endings.

As a British expert, Dr. John Seale, wrote in the August issue of the Journal of the Royal Society of Medicine, "a virus which successfully crosses the...barrier is often...lethal to the new species, though harmless to its natural host.

"The virus of African swine fever does not inconvenience the African wart-hog," Seale continued, "but it kills nearly all infected European pigs."

A virus that merely causes mouth sores in monkeys gives people deadly encephalitis, Merigan says. And the viruses of Lassa fever, Marburg-Ebola disease, and South American hemorrhagic fever peacefully inhabit rodents, but rapidly kill people.

Did HTLV-III really scale the species wall? Merigan says, "Our best epidemiologic evidence suggests that (the first cases of AIDS) occurred in Africa." And he agrees with Dr. Max Essex, chairman of the cancer biology department at the Harvard University School of Public Health, that the original source of HTLV-III could have been African monkeys.

Essex has found a virus remarkably similar to HTLV-III in Green monkeys that dwell in the same African countries, Zaire, Congo, Rwanda, and Burundi, where scientists think the outbreak of human AIDS began.

These Green monkeys, Essex finds, are not sick.

"We'd like to know why an agent is so well controlled by the monkey," Merigan says, "as that may give us leads on how to control the human disease."

Essex's hypothesis of Green monkeys as the source of the AIDS virus is "the most attractive theory that exists," says Dr. Peter Drotman, an epidemiologist from the national Centers for Disease Control.

Not all researchers agree. Engleman emphasizes that the AIDS virus seems to have a "special affinity" for the CD4 receptor on the human T4 cell.

"I'd argue that the only animals that would be infectible (with HTLV-III) are those with a CD4 molecule that is very similar to that of humans," he said.

As with other viruses that have found people a convenient place to live, Engleman explains, the ability of HTLV-III to mesh with the CD4 receptor is an unlucky accident of evolution.

Robinson is also cautious about an animal-AIDS connection. "Most viruses have a fairly narrow host range," he says.

It is possible that a monkey virus closely resembles human HTLV-III, he says, but that doesn't mean there was a transfer.

The virus that causes hepatitis in humans, he explains, has relatives among those that produce hepatitis in ducks, woodchucks, and ground squirrels.

The different versions of hepatitis disease are not cross-contagious among the species, yet similar coding within the genes of each of the responsible viruses suggest they had a common ancestor, he says.

But differences in the viral genes are enough to indicate that thousands or even millions of years have elapsed since that ancestor was around. And the same may be true for HTLV-III, Robinson says.

Deciphering the genetic code of the monkey virus to see if it is identical to the code of HTLV-III would decide the issue. The sequence of genes in HTLV-III is already known.

Still, even if the Green monkey virus is only a relative of the human AIDS virus, a monkey version of AIDS could help with a human vaccine.

Rhesus monkeys, which come from India, can be stricken by a virus that, like HTLV-III in humans, suppresses their immune systems. They die of infections, as do human AIDS victims. And Dr. Murray Gardner, chairman of the pathology department at the University of California at Davis medical school, has already fashioned a vaccine from killed, whole virus which protects healthy monkeys from getting the disease.

Gardner points out that the virus he is studying, called Type D, is only a distant relative of either the human AIDS agent or the virus in African Greens. But he hopes his success with the Rhesus will suggest strategies for human AIDS patients.

An even closer monkey model of human AIDS may be available. Essex has found that Rhesus monkeys also harbor a "simian T cell leukemia virus" (STLV) which does suppress their immune responses.

STLV, which makes the Rhesus sick, closely resembles the virus that apparently does not harm African Green monkeys. They could indeed be the same virus, Essex says.

The proteins of STLV, HTLV-III, and the Green monkey virus are all the same size, he says. Moreover, human antibodies to HTLV-III recognize both monkey viruses. The converse is also true: antibodies in blood taken from infected monkeys bind HTLV-III as strongly as either of the monkey viruses.

He plans to dissect the surface proteins of the monkey and human viruses so he can find the critical regions for immunity.

"It would be logical to take a piece of the virus that stimulates immunity in monkeys and use it as a vaccine for people," Essex explains.

Isolating a specific piece through techniques of genetic engineering, Gardner adds, would avoid the risks of vaccinating with the whole virus of such a deadly disease.

Yet one potential problem in developing an effective vaccine against AIDS has already surfaced.

The genes of HTLV-III differ among viruses obtained from different AIDS patients, and even the samples from a given patient have shown genetic variety.

These findings worry scientists. Genes determine the protein make-up of viruses, and the proteins that coat a virus are usually the attack targets for the immune system, and thus are the best candidates for a genetically engineered vaccine.

If these coat proteins vary among AIDS viruses, it will be hard to make a vaccine that will stimulate immunity against all the different viral varieties.

But Robinson claims the fear of failure is premature. He points out that gene differences are two steps removed from the resulting protein shapes which the immune system sees—genes have some leeway to vary, he says, without having their final protein products come out so altered that antibodies can't recognize them.

Genetic diversity also occurs among strains of hepatitis viruses, Robinson says. Yet a promising, genetically engineered hepatitis vaccine is already being tested in people.

Monkeys might have started the AIDS epidemic in people, but that says little about how the disease jumps from one person to another.

On the subject of transmission, the overwhelming consensus is that the HTLV-III virus is not adept at entering bodies. The disease AIDS is just not easy to catch.

According to Essex, the medical literature documents that Green monkeys have passed other, non-epidemic diseases to humans: notably Marburg fever, probably when the monkeys bite people who try to capture them; and jungle yellow fever, courtesy of a mosquito intermediary.

Yet this bridging of the species gap would be a rare event in the evolution of a virus, one that might start an epidemic but could not sustain one, Essex emphasizes.

"Once it crosses the species barrier," he says, "then people obviously transmit (the AIDS virus) to each other."

And whereas a monkey's bite could have been the isolated accident needed to inject the virus into the human community, scientists agree that saliva is not a good vehicle for transferring HTLV-III.

For one thing, Essex says, the amount of AIDS virus in human saliva is orders of magnitude less than the amount of cold virus present in the saliva of someone with the sniffles.

For another, Engleman adds, HTLV-III becomes frail outside the protective salinity of body fluids. Tap water breaks it apart; drying quickly destroys it.

Factor the fragility of the virus with its low numbers in saliva, and the resulting probability makes it unlikely that people acquire AIDS from a peck on the cheek, Essex says. A bite raises the probability, he says, because it introduces blood into the equation.

The final case against saliva as a transfer route for HTLV-III is statistics.

"The epidemologic pattern would look very different," Essex says. "More women would have AIDS, and more kids would have gotten it from their parents."

Another assurance that AIDS, although deadly, is not a particularly infectious disease is that health care workers have not contracted it through their contact with patients. Doctors and nurses who treat the disease would be especially likely to acquire AIDS were it easily transmitted.

In a prospective study at San Francisco General Hospital, 300 workers exposed to AIDS patients and lab specimens are being monitored for the presence of antibodies to the virus, according to the principle investigator, Dr. Julie Gerberding. The study has been going for one and a half years, and, so far, the only people who have tested positive are those who are gay, have bisexual partners, or belong to another high risk group for contracting AIDS.

And of 1758 American health care workers enrolled in similar studies, the CDC reported on September 27 that only two have acquired the AIDS virus through accidental exposure to patient blood: a female worker stuck herself with a contaminated hypodermic needle on two separate occasions, and a male lab technician cut his hand while handling a blood sample, and also stuck himself with a needle.

Both have had symptoms of swollen glands that often precede AIDS, but neither has yet developed the full blown disease, nor has the one British worker who tested positive for HTLV-III antibodies after a needle injury.

The CDC has concluded, in an editorial in its Morbidity and Mortality Weekly Report, that the risk of acquiring AIDS by occupational hazards in health care is "extremely low'—much less than the threat of hepatitis through needle accidents.

Certainly, Gerberding says, doctors and nurses take precautions around AIDS patients if a particular test or treatment they are giving risks accidental contact with blood or other virus-bearing body fluids.

At San Francisco General and at Stanford University Hospital, care givers don gloves to collect blood, stool, urine, or other secretions, and label such samples "Blood Precautions" (Stanford) or "H/a" (hepatitis/aIDS, San Francisco General). Hands are washed before and after any patient contact.

It is not unreasonable to wear gloves and a gown with AIDS patients, says Stanford's Robinson. But, he adds, gloves are not really necessary unless there is a break in the skin.

And hospital guidelines recommended by the CDC state that masks and gowns are needed only if the worker is likely to be soiled by spraying blood or vomit.

Simple hand washing is usually an adequate precaution, Robinson says, and when he treats AIDS patients, he often leaves it at that.

"We should prevent turning AIDS patients into untouchables," he says.

Hospital practices adopted for AIDS are similar to those used for handling people with hepatitis, since hepatitis B and AIDS share similar modes of transmission, Robinson points out.

In the western world, both diseases often strike intravenous drug abusers who exchange blood when they share needles, and homosexuals exposed to each other's blood through anal intercourse.

But in underdeveloped countries, hepatitis has a different pattern, Robinson says.

Mothers probably pass the hepatitis B virus to their newborn children, he says. Rather than causing an acute infection with fever, jaundice, and stomach pain, the hepatitis virus stays "silent," until accumulated insults to the liver kill the host, at age 40 or 50, with cirrhosis.

Perhaps a similar history for AIDS, with different, more silent symptoms, will be uncovered in Africa, Robinson speculates.

Primitive cultures might not recognize AIDS, but would think victims were dying of pneumonia or the other opportunistic infections, he says, "so it's hard to say if AIDS hasn't been around."

According to Drotman of the CDC, only one in fifteen of American AIDS victims are women, whereas available records show that the number of cases in African women and men is equal.

This different incidence suggests that AIDS, like hepatitis, takes a different pattern of transmission once it enters developed countries, Robinson says.

He doesn't think AIDS will spread as rapidly through heterosexuals in America as it has in the homosexual community, because many gays have been promiscuous.

"We're talking about several thousand sexual partners in one lifetime for some gays," he says.

Yet Engleman notes that we may not have waited long enough to see AIDS march through all segments of the American population, as the virus's incubation period can be five years or longer.

Knowing more about the habits of HTLV-III could be the key to halting the virus in its tracks.

To unravel the "natural history" of the AIDS virus—when it first appears in the blood, how long it takes for it to cause symptoms, how it passes from one person to the next—Robinson is watching Stanford AIDS patients and their contacts.

He can directly test for HTLV-III in their blood with a DNA probe. The probe's sequence of DNA bases matches the corresponding genetic code in the virus, so the probe sticks specifically to HTLV-III.

In contrast, the test now used to screeen blood is indirect. It measures the antibodies which HTLV-III has stimulated the body to produce, not the virus itself.

Robinson says about 100 investigators have the probe. "We'll need work by many labs to find the answers" to how the AIDS virus behaves, he says.

But, he adds, focusing solely on the behavior of HTLV-III may be too narrow of an approach to AIDS.

Robinson suspects that concurrent infections may sway the course of HTLV-III. "People are looking for what leads to activation of the AIDS virus in T cells," he says.

Engleman has found that HTVL-III does not readily invade "fresh, resting T4 cells" taken from the blood and grown in tissue culture. First, he says, the cells must be turned on by an immune challenge.

Early in the search for the cause of AIDS, he says, a popular idea was that repeated infections somehow render the body more susceptible to the disease. Many doctors pointed out that promiscuous gay men frequently contract many sexually transmitted diseases, and are exposed to sperm which may suppress immunity when introduced into the lining of the rectum.

A new version of this hypothesis of weakened immunity is again gaining credence, Engleman says. "In a way, the argument is coming full circle."

A MODEL BABY'S LIFE THREATENED BY RARE DISEASE

STANFORD—

Taylor Zak is six months old, weighs 20 pounds, smiles about 90 percent of the time and is alert and playful. In short, he appears to be a perfect model of a healthy baby.

But he is not healthy. Taylor suffers from a disease so rare that only five other cases have been diagnosed in the world. It is also a disease that is almost invariably fatal; most of its victims die in the first year of life. Unless medical science finds a cure for the disease, Taylor's life expectancy is probably no more than two or three years at best.

However, Taylor's apparently healthy condition is evidence of a medical breakthrough of sorts in the treatment of the disease at Stanford University Medical Center, where the baby was transported a few days after birth in Santa Cruz. Dr. John Kerner, assistant professor of pediatrics at Stanford, calls the treatment "state-of-the-art parenteral nutrition." Without it, Taylor would either be dead or extremely weak and emaciated.

What Taylor has is called congenital microvillous atrophy. It is an extremely rare subgroup of a rare disease called familial enteropathy or lethal protracted diarrhea that has the same symptoms: extremely severe diarrhea from birth, resulting in weakness, dehydration and ultimately death. The diseases appear to be hereditary.

Taylor developed severe diarrhea shortly after his birth March 20 in Dominican Hospital in Santa Cruz. He went home from the hospital with his parents, Richard and Kelly Zak of Santa Cruz, but they took him back to the hospital almost immediately because of the diarrhea. Doctors there couldn't determine what was wrong and transported him to Stanford, where he has been ever since.

Stanford physicians couldn't be sure about the illness, either, until an electron microscopy performed on a small intestinal biopsy revealed microvillous atrophy, which means that Taylor essentially has no functioning villi in his intestinal tract. (One reason the diagnosis of microvillous atrophy is so rare is the rarity of sophisticated diagnostic techniques such as electron microscopy.)

Villi are minute hairlike projections that are present by the millions in the small intestines of most people. Since the villi's normal function is to absorb nutrients from food passing along the intestine, their lack means that Taylor can get no nutrition from food.

Stanford has solved that problem by intravenous feeding that supplies all the vital nutrients for Taylor. Such treatment is standard, but it has worked spectacularly well in Taylor's case because of experience Stanford had earlier with victims of familial enteropathy. Kerner says that experience contributed to a "mistake-free" treatment that has worked so well that Taylor is "actually too fat" at present.

The IV feeding, however, has solved only the nutritional problem. The diarrhea remains, and so does the threat of fatal infection—the villi in a normal body also act as a protection against the invasion of intestinal bacteria that normally live in the large intestine. Without that protection, Taylor is in constant danger. "He's already had four life-threatening infections that came through the gut," Kerner said.

Kerner describes Taylor's problem as an "immature gut," one that just didn't develop fully in the womb. He said Stanford physicians have tried a number of drugs in an attempt to aid the development, but nothing has worked so far.

If further drug treatments don't produce the desired result, Taylor will go home to Santa Cruz about Nov. 1. He will remain hooked up to his intravenous feeding equipment, although it is hoped that eventually he'll be able to leave it eight hours out of every 24. Kelly Zak has already taken all the necessary training for administering the IV feeding, and she will have nursing help at night.

All of that, of course, is expensive. Marla Diamond, assistant clinical nursing supervisor in pediatrics at Stanford, says that the cost of Taylor's intravenous feeding nutrients alone will be $100 a day. Costs of equipment and nursing help will bring the total to $50,000 a year, according to Kelly Zak.

Insurance has paid most of Taylor's bills so far, but the insurance is expected to run out soon. In an attempt to help pay for Taylor's home treatment, the Zaks have set up a trust fund at the Bank of America in Capitola.

Taylor will be happy at home, but he's also happy in the hospital, despite the diarrhea and his ever-present IV hookup. He plays happily with his toys and stuffed animals, gurgles at nurses and volunteers and gets ecstatic at the appearance of his mother. Kelly Zak is at the hospital daily—she quit her job in Santa Cruz as soon as Taylor was hospitalized—and Richard Zak is there on weekends and during the week whenever he can spare a few hours from his job with a Santa Cruz plumbing supply company.

CALIFORNIA TO REQUIRE THAT HOSPITALS SEEK DONATIONS OF ORGANS

STANFORD—

California hospitals will be required as of Jan. 1 to ask families for organ donations whenever a patient dies.

The rule is the result of a new state law signed recently by Gov. George Deukmejian. The law is intended to increase the availability of scarce organs for transplants by taking the onus off physicians and hospital staffs who are reluctant to intrude on a family's grief.

The law requires general acute hospitals in the state to "develop protocols for identifying potential organ and tissue donors in a specified manner." In addition, hospitals will be required to notify organ or tissue procurement organizations of donation of organs.

The new rule was welcomed by Dr. Stuart W. Jamieson, associate professor of cardiovascular surgery and director of Stanford University Medical Center's heart-lung transplantation program. "We only retrieve a small percentage of the available organs for transplantation purposes," said Jamieson. "The law will help increase significantly the public consciousness on this life-saving issue."

Researchers such as Jamieson have been saying that the transplant picture, glowing with success rates as high as 94 percent for some organs, is clouded by inadequate procedures for finding donors.

Stanford, which has the largest heart-transplant center in the world and is one of the few doing heart-lung tranplants, estimates one-fourth of the people in need of transplants die waiting for organs.

"That's the biggest anxiety, the thought of coming here and dying," said Stanford's Mary Burge, the clinical social worker on the transplant's screening team.

State Assemblyman Bill Leonard (R-San Bernandino), legislative sponsor of the rule, noted the growing awareness of the need for more organs throughout the United States and the need to educate Californians further on the issue.

Quoting estimates from the Regional Procurement Agency of Southern California, Leonard said 10,000 people are waiting for kidney transplants nationwide, 175 for livers, 150 for hearts and 30 for pancreases.

New York and Oregon are the only other states so far to require that organs be solicited from surviving families.

The new rule also stipulates that hospitals should "encourage reasonable discretion and sensitivity " to the family circumstances in discussions regarding organ donations, including religious concerns that may prevent donations.

City desks and science writers: You are cordially invited to attend this symposium October 17, 1985 in Stanford Medical School's Sherman Fairchild Auditorium. The conference will focus on molecular aspects of disease. Program copies available on request if not included with story.

GENES AND DISEASE SYMPOSIUM TO BE HELD AT STANFORD OCTOBER 17

STANFORD—

A day-long symposium on "Genes and Disease" will be held Thursday, October 17, sponsored by Beckman Instruments, Inc., in celebration of the 50th anniversary of the company's founding.

The symposium, organized by the Stanford Center for Molecular and Genetic Medicine, will be in the Sherman Fairchild Auditorium, beginning at 8:15 a.m. with welcome remarks by Stanford University President Donald Kennedy.

Featured topics will range from the molecular biology of insulin production, the genetic regulation of viruses causing human leukemia and AIDS (Acquired Immune Deficiency Syndrome), to the latest research on the molecular basis of how bacteria invade animal cells.

"We now begin to change our perspective on disease," said Nobel prize winning biochemist Paul Berg who will preside at the meeting. "Disease is a defect in the molecules that make up our cells."

Understanding cellular regulatory processes in chemical and molecular terms, Berg said, holds promise in enabling man to intervene and repair abnormalities that cause disease. Berg directs Stanford's $50-million Center for Molecular and Genetic Medicine. When completed in 1987, the center will house several departments devoted to research and applications of molecular approaches to treatment of disease.

The Beckman symposium is the third of its kind held at a major university in celebration of the company's 50th anniversary. Previous symposia were held this year at City of Hope Hospital and Medical Center, Duarte, Calif., and Rockefeller University, New York.

The company, founded in 1935 by Dr. Arnold O. Beckman, a noted scientist, has pioneered in the development of indispensable analytical tools for chemistry, medicine, industry, agriculture and environmental technology. In 1982, the company merged with SmithKline Corporation to form the SmithKline Beckman Corporation.

Through the Arnold and Mabel Beckman Foundation, Dr. and Mrs. Beckman have supported the development of the department of biochemistry's laboratories in Stanford's new center.

The day's schedule will include:

8:45— "The molecular biology of insulin production"—Dr. Donald Steiner, professor of biochemistry and molecular biology, University of Chicago, and senior investigator, Howard Hughes Medical Institute;

9:40—"Genetic regulation and pathogenesis of retroviruses: the human leukemia and AIDS viruses"—Dr. William Haseltine, associate professor of pathology, Dana Farber Cancer Institute, Harvard Medical School;

11:00—"Development and use of a human chromosome map"—Dr. Uta Francke, professor of human genetics and pediatrics, Yale University School of Medicine;

1:10—"Using bacteria to express gene products of interest to biomedical research and development"—Dr. Martin Rosenberg, vice president for biopharmaceutical research and development and director of the molecular genetics department, SmithKline Beckman, Inc.;

2:00—"Oncogenes and retroviruses"— Dr. Harold Varmus, American Cancer Society professor of molecular virology, University of California, San Francisco;

3:10—"Molecular basis of bacterial invasion"—Dr. Stanley Falkow, professor and chairman of medical microbiology, Stanford.

WAYS TO CUT MEDICAL COSTS BUT NOT QUALITY INCREASINGLY IN DEMAND BY PHYSICIANS

STANFORD—

Decision-making aids—tools to help physicians more accurately diagnose and pinpoint the most appropriate therapy in today's cost-conscious environment—will be increasingly in demand, according to Dr. Harold Sox, associate professor of medicine at Stanford University School of Medicine.

One such tool, called a clinical prediction rule, has come of age, so to speak, with a recent *New England Journal of Medicine* article by Sox; Dr. John Wasson, Dartmouth Medical School; Raymond Neff, University of California, Berkeley; and Dr. Lee Goldman, Harvard Medical School.

"Clinical prediction rules are ways for physicians to maintain the quality of medical care while reducing the cost to patients," Sox said in an interview.

"We wanted to call attention to the existence of these rules, and to establish standards with which to design them," he added.

A clinical prediction rule, Sox said, is actually just a guide, data collected from individual patient cases over time and from experience, to help physicians in predicting events among their patients. They serve to reduce the uncertainty in diagnosis, thus eliminating the need for physicians to order tests and possibly even hospitalization, all which add to medical costs.

For example, Sox said, if a patient is complaining of chest pains, there is a certain probability that he may have a heart attack. If the physician is aware of the clinical prediction rule that states that probability, he can immediately prescribe appropriate therapy rather than subject the patient to a series of tests and diagnostic procedures.

"It's not that physicians don't know," Sox explained. "It's just that there is a great deal of uncertainty in medicine and in order to protect patients, physicians may order tests and hospitalization to confirm their diagnosis. Clinical prediction rules help them achieve that goal without the extra expense."

However, Sox warned, physicians should adopt these rules—of which there are about 50—with caution. "The rules are only a guide, and should not be the sole element involved in decision making. Physicians should rely on their own clinical instincts and expertise as well. The rules simply provide a broad data base of experience for those who may not have as much personal experience."

Before adopting a rule for their own patients, Sox and his colleagues wrote, physicians should consider factors, such as the makeup of the patient population from which the rule was derived, in order to ensure that the rule is applicable to their own patients.

In the article, published in the Sept. 26 issue of the journal, the authors looked at 33 clinical prediction rule reports. They considered the way the rules were derived and how applicable they were to patient care. In order to be most useful to physicians, they concluded, the rules must comply with certain standards in regards to collecting and analyzing the data.

Key to the usefulness of a rule, Sox said, is to try and apply it to as many patients as possible to see if it really is relevant.

"We hope this is *the* standard-setting paper," Sox said. "We hope future studies will look to ours as a guide to design and evaluate a clinical prediction rule."

COMMISSION TOLD OF MEDICAL HAZARDS OF MARS MISSION

STANFORD—

Medical hazards of a round-trip mission to Mars are significant, but not insurmountable, a Stanford University Hospital surgeon told the National Commission on Space Wednesday, Nov. 20.

Dr. William DeCampli, a surgical resident who also is an astronomer, discussed the medical aspects of a Mars mission as part of the commission's three-day meeting at Stanford University Nov. 18-20. The 15-member commission appointed by President Reagan is charged with developing a long-term space policy for the United States.

Research done in the next two decades of preparation for the manned flight to Mars should answer a lot of currently puzzling questions, he indicated.

Medical problems on the trip to Mars would certainly include the well-documented difficulties of weightlessness such as bone and muscle loss, Dr. DeCampli acknowledged. He predicted, however, that those drawbacks would be solved by scientists working on the Space Station due to be in orbit by 1995.

The Mars mission would take at least three years, and man has never spent more than a year in outer space. Soviet astronauts who returned from 237 days in space reportedly were carried from their craft because their bones and muscles had weakened and could not support them. Little is known about that mission or astronauts, however. The longest American space flight was the 84-day Skylab mission.

The greatest health risks to astronauts, according to Dr. DeCampli, may be infectious diseases, psychological problems of isolation and confinement, radiation exposure, accidental injuries and everyday health problems.

Dr. DeCampli, who holds a Ph.D. in astronomy, also is a member of the National Academy of Sciences task force on "Major Directions in Space Science 1995-2015."

A fourth-year resident in general surgery, Dr. DeCampli has served as an advanced research fellow in cardiovascular surgery. As a fellow in astronomy, Dr. DeCampli conducted both observational and theoretical studies of planets and stars.

Astronauts will be faced with health problems from inside and outside of their spacecraft—as well from within their own bodies, he said.

Some problems arise because spaceships are small, closed environments, DeCampli said, but lessons learned on submarine missions can be applied to space travel. Other challenges will surface because of "novel recycling techniques and waste disposal methods."

"Any time you have a closed system, you'll find a microbe that likes it," he said, recommending that people be included in a mandatory trial run of the spacecraft's circulatory systems conducted to determine whether those bacteria cause disease or death.

This test of the spacecraft also could help predict the stress of isolation and confinement.

"Show us that mental health can be maintained inside this glorifed elevator for (the) three years" it takes to get to Mars and back, he challenged in his prepared statement.

The mental stresses of space travel may be considerable, but "personally, I think that the uniqueness, sense of achievement and, frankly, prospect for recognition would keep the crew motivated."

Although astronauts are exceptionally fit and are carefully screened for health risks before being selected, they still run the risk of certain medical problems just because they are human.

Acute appendicitis, gastrointestinal disorders, heart trouble and cancer may happen at any time during the mission, Dr. DeCampli said, and preparations must be made to treat some of the more probable maladies. Each crew member runs a good chance of "contracting a condition that normally would have put him or her in the hospital on the earth," he indicated.

Accidents normally treated on earth must be anticipated, too, Dr. DeCampli continued. The gravity field of Mars is about a third of that of Earth, "enough to provide ample force for fatal falls and crush injuries."

An astronaut could be wounded in a construction accident on Mars—or an explosion on the spacecraft could injure him before he gets there.

Will surgeons be able to operate in space? "A decision to treat moderate to severe trauma implies a major commitment to critical care medicine, perhaps for a long time," Dr. DeCampli stated. "I am certain that the surgeon on board the Mars ship will be prepared to perform emergency procedures, but they are only the beginning of care for the trauma victim."

FIRST MULTI-LEVEL PARKING STRUCTURE AT STANFORD BEGINS CONSTRUCTION

STANFORD—

Groundbreaking for the first multi-level parking structure on the Stanford University campus will take place Monday, Nov. 25, near the medical center.

The new structure will be built in the area now occupied by the "A" and "C" permit parking lot surrounded by the anatomy building, Roth Way and Campus Drive.

Those currently using the parking lot will be temporarily redirected to lots within walking distance to the medical center. They include a new lot between the anatomy building and the museum, street parking on Museum Way and an extension of Roth Way, the lot bordering Quarry Road, the lot north of the heliport, a temporary lot between Pasteur Drive and Mayer cancer research laboratory and a new lot at the corner of Campus Drive and Welch Road.

The present anatomy building parking lot holds 260 cars; the new structure will hold 1,050 cars when completed, said Jonathan Ryan, project manager from the facilities project management office.

The new structure will require one volleyball court to be permanently relocated. In order to make it accessible and "user-friendly," Ryan said, Roth Way will be extended to Palm Drive, and Quarry Road will be extended to the parking structure. "We'll be quadrupling the use of the land," he said.

Construction is scheduled to take 16-18 months. However, an estimated 500 parking spaces will be available about 10 months into the project, Ryan said.

The new structure, with a price tag of $9.4 million, will be five stories high with a total of 40,000 square feet. The design calls for a "step-back" arrangement--each floor receding from the one below--in order to create a less imposing presence, Ryan said. "Our challenge was to incorporate a parking structure in a non-industrial environment," he explained. "It has to be visually unobtrusive."

The structure was designed with the safety of its users--an estimated 80 percent of which will be medical center personnel--in mind. It will contain two glass elevators, and five stairwells all located on the outside of the structure. Police pulls will be located throughout the well-lit structure.

The structure was designed by Watry Engineering, Inc. of Redwood City, one of eight firms that submitted designs. Their design was chosen by a jury of architecture and other faculty and staff.

PATIENT RELATIONS ASSOCIATES PROGRAM CELEBRATES FIVE YEARS

STANFORD—

Stanford University Hospital's patient relations associates program celebrated its fifth-year Sunday, Nov. 17, with a reception at the Buck Estate attended by more than 100 associates, staff and guests.

The all-volunteer effort was started five years ago by community and patient relations director Jeanne Kennedy to "provide a needed personal link" between patients, families and the hospital. It now functions as part of the hospital's community and patient relations department.

It was no simple undertaking, Kennedy recalled, because there was no budget or staff to run the pilot project. Working with Diana Roth, a hospital auxiliary member, and Sandra Perkins, then director of patient admitting, a group of volunteers was formed to test the idea as a pilot project. Roth served as chairperson.

Later when a hospital committee evaluated the project, it was determined a success. The program has been growing ever since.

Today there are 24 patient relations associates, five of whom are on-call round the clock. They meet with families of patients brought to the hospital by critical care transport or Life Flight helicopters, and they are available to all hospitalized patients and their relatives. The volunteers range from their mid-twenties to their sixties and work from four to thirty hours a week.

"These are volunteers who are professional in every way," said Kennedy. "I am impressed with the caliber of people we have working here."

"The associates meet with patients when they're admitted to the hospital, make them feel at home, inform them of available services, visit them during their stay, solve problems and act as a referral source," explained Donna Pronko, patient relations coordinator.

Sometimes issues are emotionally charged and sometimes problems are grave. At other times patients simply need a friendly ear. "We answer questions about television sets, phones, food, smoking, and housekeeping all of the time, " said Caroline Pease, one of the original associates. "Other issues are more sensitive such as helping to clear up misunderstandings between patients and doctors.

"Often times we help patients to become more assertive in asking their doctors and nurses questions because patients may feel intimidated by medical personnel," Pease said.

"There is such a diversity of activities," added Mary Ives, who has also been with the program from the start.

"We're trying to be liaisons with the patients and the medical staff, chaplaincy services, social workers, dietary staff, and others. We get to know a lot of people," Pease said.

Patient relations associates get calls from nurses and others who feel a visit from one of them would help ease a tense situation or brighten the spirits of a patient from out-of-town or one who has no visitors.

To handle the variety of personalities and situations they encounter, new volunteers first attend a training orientation and tour of the hospital, followed by six sessions of communication workshops, four to six sessions of on-the-job-training, infection control training, fire and safety disaster drills, and monthly meetings, Pronko said.

However, it was a lot of on-the-job-training for the first four associates. "We learned as we went along," recalled Pease. She credits the building of resources and monthly exchange of ideas to the success of the program.

The associates volunteer for a number of different reasons, Kennedy explained. "The program gives some the professional credentials they need to start a paid career. Others join because their own job doesn't offer enough involvement with people. And some have had a lot of hospital experiences with family members who have been sick, and they know a lot about the problems patients go through and want to help with that. Also it's an affective way for people who have not gone out into the work environment, but who have had a lot of mature experience in life, to apply their knowledge."

Although they may have different reasons for joining the associates share certain prerequisites: personal experience with illness, good communication skills, an empathetic, warm, and friendly manner, and the desire to help people, said Pronko.

"It's a rewarding job," Pease feels. "There are a lot of grateful people and I think it's wonderful when someone says to me, 'I'm doing fine now' and thanks me."

At the Sunday reception Roth, Pease, and Ives were honored for their five-year involvement with the program. Kennedy also paid tribute posthumously to the fourth original member of the group, Mrs. Lucile McNichols who died in March of 1984.

The community and patient relations department donated an Indian Pechwai painting on fabric in honor of the patient relations associates, in particular the four original members. The painting, from the Krishna-Lili School and painted around 1880, will be displayed at a hospital location yet to be determined.

Persons interested in volunteering should contact Pronko at 497-7581.

STANFORD'S PEDIATRIC PLAY NOW INCLUDES COMPUTERS

STANFORD—

The newest toy in the pediatric playroom at Stanford University Hospital is an Apple Macintosh computer.

A volunteer from Apple Computer, Inc., of Cupertino comes to the hospital every Tuesday evening carrying a Macintosh. The volunteers play computer games and try out various programs with six to ten hospitalized children each evening. Youngsters involved range in age from 2 to 18.

"The kids just love it," said recreation therapist Mary Trahan. In addition, she said, the young patients get useful training on computers.

Ellen Vanderwilt, acting director of recreation therapy, said, "The people from Apple are really wonderful. They adapt the programs according to the age of the kids."

The Apple volunteers are part of the company's Employee Volunteer Action program coordinated by Anne McMullin. She said four volunteers visit the Stanford pediatric playroom on a rotating basis.

More than 400 Apple employees have participated in the volunteer program during the nearly two years it has been in operation, McMullin said, helping recreational programs at hospitals and other institutions.

MEMORY SCHOOL HELPS HEALTHY ELDERLY FIGHT FORGETFULNESS

STANFORD—

A memory school for forgetful folks?

Yes, says Stanford's Dr. Jerome A. Yesavage, who is seeking volunteers for the two-week school he has been running for normal curious healthy persons aged 55 and over who have trouble remembering.

Yesavage thinks most, if not all, memory loss can be restored to pre-geriatric levels. The key for many persons is appropriate training, which is what he and colleagues have been trying to develop in the research project he's been running for eight years at the Palo Alto Veterans Administration Medical Center in Palo Alto.

"One of the basic facts of old age," says Yesavage, associate professor of psychiatry, "is that memory, particularly recent occurrences, decline steadily with age. The average, normal 70-year-old suffers a memory loss in the order of 20 to 40 percent," he said.

In addition, a lot of recent research indicates that anxiety about losing one's memory may in fact be a major cause of forgetfulness. If you can reduce stress, you can probably help someone improve their memory, Yesavage says.

Yesavage, instructor Danielle Lapp, and research assistant Pamela Ponich are currently seeking at least 50 persons aged 55 and above to attend classes at the Palo Alto Veterans Administration Medical Center, where Yesavage is associate director of the Clinical Diagnostic and Rehabilitation Center.

The classes are free and sponsored under a research grant from the National Institute of Mental Health. Participants must be healthy and must make a commitment to attend classes for two hours a day for two weeks. Volunteers are also needed to take tests to see how they compare with similar people who are taking the full class. These volunteers will get practical information about improving their memory but will have a shorter time commitment, Ponich said.

Lapp, who has taught the classes since the project began eight years ago, said she spends a good part of the first two-hour class explaining how the brain processes information to become memory. She also tries to reassure the six to eight students in each class that a certain amount of memory loss is normal and that even people many decades younger than the students can have problems with their memories.

Yesavage notes that most memory loss involves things that have occurred recently.

"We find elderly people that can tell you exactly what was on every shelf in a little store where they went with their parents 50 years ago, but if you ask them where their neighborhood supermarket is now, they can't remember."

Techniques taught in each class vary, and Lapp is reluctant to talk about specifics, since such advance knowledge could interfere with the research effort. Generally, however, the techniques for learning such skills as remembering names and faces might include such mnemonic devices as associating a person's name with a prominent feature.

Lapp herself gets students to remember her name by calling attention to a prominent feature—her eyes—and the physical feature associated with her last name.

"I might get students to try and visualize that 'my eyes are on my lap.' People do this kind of thing unconsciously. All we're trying to do is get them to do it consciously.

"They do get the idea that they can gain control over their memory, and that is constructive," Lapp says.

"We need all the tools we can get to become more successful in aging," says Shirley Maher, a retired Redwood City travel agent who took the course last summer. "I learned a lot about the process of memory itself, and we were certainly given every opportunity to use what we were taught," she added. "The results depend on how much you use it."

Some of the value of the program, said Lapp, is the information and support that a memory-losing senior citizen isn't alone. "They learn that they are not the first person to have forgotten the names of their grandchildren, and this relieves tension and helps them learn to improve their memory," she explains.

Maher said that members of her class have continued on their own to meet once each week to practice what they've learned in school.

The VA study is reserved exclusively for persons over 55, but Yesavage notes that even younger people can benefit from mnemonics or other similar training.

While the senior citizens can gain back a fifth or more of their memory loss, younger persons can actually achieve a net gain if they practice the techniques educators have been developing for many years.

Persons interested in finding out about the current study at the VA may call Ponich at 493-5000, ext. 4570. There is no upper age limit, and Ponich noted that the oldest volunteer so far was a man aged 95 who did very well in the class.

Volunteers must not be suffering from any organic memory loss, such as senile dementia or Alzheimers disease, she said. Persons interested in studies for those conditions should call 493-5000, ext. 5150.

NURSING CARE, COSTS INCONGRUOUS WITH FEDERAL REIMBURSEMENT RATES, STANFORD STUDY SHOWS

STANFORD—

A Stanford study shows that the federal government's reimbursement system for Medicare patients' health care services does not accurately reflect nursing care and costs in hospitals.

The results of the study were included in a report to the secretary of U.S. Department of Health and Human Services by the Prospective Payment Assessment Commission, established to evaluate the effectiveness and validity of the diagnostic related group (DRG) classification system that went into effect in 1983.

One conclusion of the Stanford study and the federal report is that nursing care and costs vary greatly between and within DRGs and that the reimbursement rates do not correspond with those costs, said Malinda Mitchell, acting director of Stanford University Hospital nursing service and one of the study's authors.

Mitchell presented the Stanford study last week at the annual Nursing Research Rounds.

DRGs were developed as part of the government's prospective payment program, aimed at capping health care's spiraling costs. Each of 468 classifications is based on a different disease diagnosis, and has a pre-set reimbursement rate. If a hospital spends more per patient, the theory goes, it loses income. If it spends less per patient, it pockets the extra payment.

But after determining hours of direct nursing care and nursing costs for 10 DRGs during a five-month period, Mitchell said, the system doesn't seem to be working.

Consider, for example the DRG for patients with lymphomas or leukemia involving a surgical procedure. The number of direct nursing care hours ranged from 24 to 709 hours. The cost of those hours ranged from $487 to $14,386.

"The problem is that the resources used are not homogenous with the actual costs," Mitchell said.

That disparity could be resolved, Mitchell continued, if the government took into account severity of illness when determining reimbursement rates.

"The evidence suggests that Medicare's current method of allocating nursing cost by patient day does not adequately account for a hospital's resource use relative to case mix," the report to the HHS secretary stated. More information, it concluded, is necessary to determine how to "correct nursing resource misallocations."

Mitchell and one of the co-authors, Joyce Miller, associate director of nursing, are continuing to analyze data to expand their study results to include more DRGs. They hope to be able to use it to "educate the people involved in making legislation," Mitchell said, as well as to use it as a comparison with other hospitals and over time to see if changes in health care and treatment effect nursing care.

SCIENTISTS WORKING ON AN EYE TEST FOR SCHIZOPHRENIA

STANFORD—

Researchers at Stanford will be looking into the eyes of schizophrenics to search for differences in the response to light in an attempt to devise an objective measure of their illness.

The study on schizophrenia is part of a larger project funded by a grant recently awarded to Michael Marmor, head of the division of ophthamology at Stanford University School of Medicine, who will be collaborating with psychiatrists at Stanford and the Palo Alto Veterans Administration Medical Center.

In an effort to develop noninvasive ways to study the eye, Marmor will be looking at the electrical signals generated by the light-sensing cells of the retina and its supporting tissue.

"We can record from the surface of the eye to see disease inside," he said in an interview.

He said a computer system has been programmed by the psychiatrists and is ready to analyze readings from the eyes of schizophrenics, as compared to the eyes of normal volunteers.

Scientists have linked a part of the retinal response to light with dopamine, one of the brain's chemical messengers that is also used by some cells within the retina.

Dopamine is suspected by researchers to be involved in schizophrenia. And any abnormality in brain dopamine might also be reflected in the retina, which is more accessible to measurements, Marmor said.

He explained that a contact lens carrying an electrode can eavesdrop on the signals created by retinal cells as they convert light into the electrical messages that they relay to the brain.

With a research team of psychiatrists that includes Dr. Philip Berger, director of the Norris Mental Health Clinical Research Center, Dr. Adolf Pfefferbaum, and Dr. Gail Schechter, Marmor said he and his colleague Dr. Peggy Hock hope to find within the eye "an objective criterion for diagnosing or following schizophrenia."

Marmor will also use his new grant to peer into the function of the pigment epithelium, the dark-colored lining of cells that nourish and protect the clear cells of the retina.

"When the pigment epithelium breaks down, as it does in a number of eye diseases, visual function is affected," Marmor said.

The pigment epithelium, like the retina, produces electrical signals that can be read at the eye surface. And learning more about the responses of cells in the pigment epithelium could lead to specific, noninvasive tests "to see if it is working properly," he said.

The National Eye Institute is awarding a total of $206,847 to Marmor for his studies of the electrical signals of the eye, with $69,141 for the first year of work.

This new grant runs concurrently with another award, now in its second year, by the Institute to Marmor, which funds his research into how the pigment epithelium keeps the retina healthy and attached to the inner rear of the eye.

DOCTORS TRAIN PATIENTS TO EXERCISE SAFELY AT HOME

STANFORD—

A quickly learned, simple measurement may allow patients recovering from cardiac trouble to exercise safely at home.

The measurement, known as the rating of perceived exertion (RPE) scale, lets patients gauge the difficulty of exercise while they run on a treadmill in the doctor's office. But Dr. Martin Juneau, a Canadian cardiologist doing research at Stanford University School of Medicine, has found that the scale has practical value for patients who are exercising at home.

Dr. Juneau presented his research during a session of the American Heart Association meeting in Washington, D.C., Nov. 11.

To determine the RPE, patients run in place on a treadmill and rate the difficulty of the exercise from 6 to 20, with 20 representing complete exhaustion. Researchers monitor the patient's heart rate and other body signs and gradually increase the intensity of the exercise. Multiplying the RPE number by 10 gives a very rough indication of the exerciser's heart rate.

Although the scale seems subjective, it actually is very accurate, Dr. Juneau explained.

"People are very good judges of their own exertion," he said. "Using the RPE scale allows persons who have had heart trouble to exercise safely and take part in vigorous sports with confidence that they will not overexert." The findings apply to healthy individuals as well, he noted.

The RPE scale is accurate because it takes into account signals from the respiratory, cardiovascular and central nervous systems, as well as information from the working muscles and joints. The net result is a very accurate, highly personalized scale of how much stress the body undergoes during exercise.

"Previously," he said, "patients were taught to take their pulses periodically during exercise" or were outfitted with portable heart monitors—and were told not to exceed a certain number of beats per minute. Not only is checking heart rate impractical in sports such as swimming and skiing, Dr. Juneau pointed out, it also neglects the physiological signals included in the RPE scale.

Doctors have long known that the RPE scale is very accurate in the laboratory; patients always select the same number of the scale when their heart rates and other body signals reach certain points. But until now, doctors doubted that the scale was accurate enough to be used at home, because laboratory results often differ from real-world experience.

To find out, Dr. Juneau strapped portable heart monitors and recorders onto patients and sent them home. Patients wore the monitors continuously for three days; all walked or jogged and noted what their rating of perceived exertion was during exercise.

The conclusion? Exercising at home seems harder than exercising in the laboratory. As a result, using the RPE scale during home-based training gives patients worried about heart trouble an added protection against overexertion. The scale also may be helpful to healthy individuals who are beginning home exercise programs, Dr. Juneau suggested.

Joining Dr. Juneau in preparing the study, "Use of the Rating of Perceived Exertion Scale to Regulate the Intensity of Unsupervised Exercise Training," were Flay Rogers, Drs. William Haskell and Robert F. DeBusk, all of the Stanford University School of Medicine.

EMBARGOED FOR RELEASE UNTIL NOON FRI., NOV. 15

COMMON ANTIBIOTIC MAY HELP NON-INVASIVE DIAGNOSIS OF ATHEROSCLEROSIS

STANFORD—

A common antibiotic may one day help doctors see fatty deposits that clog blood vessels in people with atherosclerosis, Stanford cardiologists reported Friday (Nov. 15) at the annual meeting of the American Heart Association in Washington, D.C.

Noninvasive ways to view atherosclerotic plaques would aid diagnosis and treatment of problems caused by hardening of the arteries, according to Dr. Robert Ginsburg, physician specialist in the Center for Cardiovascular Research at Stanford University Medical Center. He directed research to show how plaques can be revealed to the gaze of magnetic resonance imaging (MRI).

MRI machines send out a magnetic field rather than x-rays to look inside people. The new technique is in use at many medical centers on an experimental basis, and already is delivering detailed views of many body areas.

But some structures, including plaque, are hard to see with MRI. The signals made by their molecules cannot be read by machines now available to medicine, Ginsburg said in an interview before the meeting.

"The problem with (currently available) MRI is that it doesn't pick up calcium, and plaque has lots of calcium," he said.

But an ordinary drug, tetracycline, readily absorbs into the fat of plaques, Ginsburg said, so it can be used to carry other compounds, visible to MRI, into the deposits.

Dr. Douglas Murphy-Chutorian, senior cardiology fellow, presented the results of experiments in which diseased arteries taken from human cadavers were soaked in a solution of tetracycline that was tagged with a marker easily detected by the MRI magnet. The tagged tetracycline was able to enhance the view by MRI of fatty deposits within the arteries, he reported.

Other researchers on the project are Drs. Steven Quay, Peter Selzer, and Lewis Wexler of Stanford.

In research to be reported elsewhere, Ginsburg has also used tetracycline as a homing device for laser surgery on atherosclerotic deposits. Dyes attached to the drug stain the plaque so it "absorbs (the laser's) light preferentially," he said, explaining, "we want the laser to damage plaque without burning holes through normal tissue."

EMBARGOED FOR RELEASE UNTIL NOON THURS., NOV. 14

CORDS WITHIN HEART MAY BE VITAL FOR FUNCTION, STANFORD RESEARCHERS FIND

STANFORD—

Threads of tissue within the heart that surgeons usually sever while replacing a failing valve may be crucial to proper pumping, researchers at Stanford University School of Medicine reported Thursday (Nov. 14) at the annual meeting of the American Heart Association in Washington, D.C.

In experiments on dogs, the scientists found that cutting cords which tether the flaps of the mitral valve to the heart wall harms the organ's efficiency.

The finding is important, said cardiology fellow Dr. David Hansen in an interview before the meeting, as "people are undergoing surgery that could possibly have detrimental side effects."

The threads, called *chordae tendineae*, are routinely cut when surgeons take out the mitral valve to replace it with an artificial one. But the old valve could be left in, according to Dr. D. Craig Miller, associate professor of cardiovascular surgery at Stanford.

Surgeons usually take out the entire failed valve since its leaflets would get "mixed up in the mechanism of an artifical, mechanical type of replacement valve," Miller said, but if a pig valve is used, in most cases it can be safely sewn to the patient's own, worn-out one.

He added that he already prefers to replace mitral valves with a pig valve, as fewer blood clots and strokes follow, compared to mechanical implants.

The mitral valve regulates blood flow from the upper to the lower left chambers of the heart. Diseased mitral valves were replaced in 12,000 U.S. patients in 1984, according to figures from the National Center for Health Statistics, and Hansen said that faculty cardiovascular surgeons at Stanford alone did 1300 such operations between 1967 and 1981.

Heart valves prevent backflow. If a valve leaks, the heart must strain to propel enough blood through the body with each beat. Heart failure can follow, requiring the valve to be replaced.

Doctors have known that the thin cords leading from valve leaflets to the heart wall hold these flaps firmly closed as the lower chambers contract to eject blood, Hansen said.

But, he said, the Stanford experiments show that the cords also reinforce the strength of the heart muscle.

As the closed mitral valve strains to hold back blood during each contracting squeeze, Hansen proposed, the valve "acts as a giant sail, catching the force of the contracting heart and tugging against its ropes"—the *chordae tendineae.*

Tension in the tethering cords is transmitted to the muscular heart wall, which would pull the heart to contract more efficiently, he said.

Replacing a mitral valve, even if the cords are cut, works well for many patients, Hansen said, because the heart often can adapt to lost efficiency by growing thicker, and by other means.

"If the heart muscle is pretty healthy to begin with, severing the cords is usually well tolerated," he explained, "but if the heart has already been compensating (for advanced heart failure), one more insult, and it's in trouble."

The heart is not just a bag that fills with and then ejects blood, it needs cross-reinforcement, Hansen said, which he thinks the cords provide.

Still, although cutting the tissue in 22 anesthetized dogs decreased the pumping force of their hearts, he said, "we'll have to show (the same effect) in humans before we can prove the clinical usefulness of keeping the cords intact."

Other researchers on the project were Drs. William DeCampli, R. Scott Mitchell, Peter Cahill, and Geraldine Derby of Stanford.

MARIJUANA'S "DAY-AFTER" EFFECTS INTERFERE WITH PILOTS' PERFORMANCE

STANFORD—

Airplane pilots who smoke marijuana may have trouble performing standard landing maneuvers as long as 24 hours after smoking a joint, concludes a new study by Stanford University Medical School and Veterans Administration researchers.

The study is believed to be the first to examine marijuana's day-after, or "carryover," effects on people who perform complex tasks, said Dr. Jerome Yesavage, Stanford assistant professor of psychiatry and behavioral sciences.

And it is thought to be only the second scientific study to examine marijuana's effects on pilots, he added, despite the fact that "during the past 10 years, there have been documented cases of marijuana use by flight trainees and pilots involved in fatal accidents . . .including a commercial landing crash at Newark airport in 1983."

Yesavage stressed that the research is preliminary and that more detailed studies are needed to clearly document how drugs affect airline pilots' performance. He is currently examining how pilots perform at various times following consumption of alcohol.

Yesavage said that the marijuana report's results should alert those concerned with airline safety to a potentially growing problem of drug-related mishaps.

But the study's implications extend beyond the airline industry, said Yesavage, who is based at the Palo Alto Veterans Administration Medical Center.

"These results suggest concern for performance of those entrusted with complex behavioral and cognitive tasks within 24 hours after smoking marijuana," he said. "Such results may be applicable to other tasks such as operating complicated heavy equipment, railway trains and switching procedures."

Although computer measurements of the pilots' landing maneuvers showed significant impairment in their performance 24 hours after smoking marijuana, the pilots themselves felt no drug hangover and reported normal alertness and mood. This suggests that a marijuana smoker's evaluation of whether or not he can do his job safely may not be objective, Yesavage said.

Yesavage and his colleagues are reporting their findings in an article published in the current issue of the *American Journal of Psychiatry*.

His collaborators on the study are Dr. Von Otto Leirer, Stanford psychiatry research associate, and Dr. Leo Hollister, professor of medicine/clinical pharmacology at Stanford University School of Medicine.

The ten experienced private airplane pilots recruited for the study carried out landing maneuvers in a computerized flight simulation laboratory located at the Palo Alto Veterans Medical Center.

Measurements of their manipulations of landing controls and of landing accuracy were carried out both before and after the pilots smoked a cigarette containing 19 milligrams of marijuana's active ingredient, tetrahydrocannabinol (THC).

11-8-85 more

The cigarette is "the equivalent of a strong social dose," the researchers said.

The pilots—all experienced marijuana smokers—were then tested at intervals approximately one hour, four hours and 24 hours following the smoke.

At each testing interval, the researchers found significant impairments in a variety of landing tasks compared to the pilots' baseline pre-pot performance.

Particularly striking, said Yesavage, was the finding that impairments persisted even at 24 hours.

The pilots tended to increase the size and frequency of their manipulations of the ailerons—the movable wing parts that provide side-to-side control of the plane—and the elevators, which provide vertical control.

Performance also fell off as reflected in measurements of the plane's runway approach—distance off-center on landing and vertical and lateral deviation on approach to landing.

"The difficulty the subjects experienced in aligning and landing precisely at the center of the runway is a particular cause for concern," the researchers said.

"The near doubling of lateral deviation on a landing at 24 hours may be an extremely serious error . . . In actual flight, where there is wind and turbulence; such errors can easily lead to crashes," the scientists said, noting that one of the 24-hour tests did include an off-runway landing.

The researchers stressed that further studies should continue in an attempt to "define the point after smoking THC at which the performance of complex tasks returns to baseline."

Similar studies examining post-alcohol performance of pilots and others entrusted with complex tasks are also needed, Yesavage said. The "bottle to throttle" guidelines—eight hours for commercial pilots and 12 hours for military pilots—may be outdated, he warned.

Studies have shown that 12 hours after an alcohol blood level of 0.1 percent, normal volunteers show impaired performance on cognitive "problem solving" tests and 24 hours after drinking alcohol people still test lower than normal on tasks involving balance and equilibrium.

Pilots' actual performance of flight tasks following alcohol consumption is just now being studied by Yesavage and his group.

"The major concern is that subtle hangover effects from drugs should be carefully documented in order to establish safe guidelines for people carrying out complicated tasks," Yesavage said.

The research was funded by grants from the National Institutes of Drug Abuse and from the Veterans Administration.

GRANT SUPPORTS RESEARCH ON LOWERING HOSPITAL COSTS

STANFORD—

Stanford Medical Center is launching a project to see if doctors and other primary care providers can become leaders in reducing hospital costs while maintaining quality care.

Support for the work comes from a two-year grant of $219,460 from the W.K. Kellogg Foundation, Battle Creek, Mich. The project, announced Nov. 8, will be conducted through August 1987 by a team headed by Dr. James F. Silverman, chief of staff at Stanford University Hospital (SUH); and Dr. Lucia S. Sommers, a research associate in the Department of Family, Community and Preventive Medicine, who will serve as project director.

Other investigators in the study are David Sakai, the hospital's chief financial officer, and Duane Walker R.N., formerly associate hospital director and director of nursing.

Researchers have been developing cost containment approaches at Stanford since August 1984. The approaches are now being refined and tested at Children's Hospital of San Francisco and San Francisco General Hospital. The major objective is to see how costs are incurred and how they might be reduced without compromising the quality of patient care, Silverman said.

Silverman, who also serves as associate dean for clinical affairs at Stanford Medical Center, said the demonstration is unusual in at least two ways. First, it will take a close look at whether the doctors, nurses and persons actually working with patients can take a leadership role in cutting costs.

Secondly, it will be searching for ways to set up processes for cutting costs, rather than simply looking for ways money is being spent needlessly or inappropriately.

"Whether or not these processes can be successfully transferred to other hospital settings is the major question the two-year study will address," Silverman said. Both he and Sommers, whose doctorate is in public health, believe that from this demonstration will come some widely applicable tools for helping hospitals implement these mechanisms quickly and efficiently.

The four cost containment projects already underway at Stanford are in the areas of orthopedics, radiology, urology and pulmonary medicine. Silverman said the process has already shown excellent promise at not only decreasing costs but also at encouraging medical staff and employees to commit themselves to the process of analyzing how services can be used effectively.

In each pilot area a professional facilitator works with a group of interested health care providers to help them raise and answer questions about the appropriateness, necessity and manner in which services are provided.

more

11-8-85

The team develops recommendations and seeks to gain support from their colleagues to make cost saving changes.

Traditionally, Silverman said, cost reductions have been mandated by administrators or hospital boards.

"It was then up to a manager of a department to figure out how to effect a particular level of savings. If a specific budget cut were ordered, the manager would be required to tailor savings to that specific level.

"The Kellogg study, on the other hand, will find ways for physicians, nurses, and other health professionals to become intimately involved in a process for both identifying and removing excess costs in a manner so as to not endanger patient care quality," Silverman added.

He said the kinds of issues being addressed in the SUH projects have been reduced length of stay of patients, economical ordering patterns of supplies and services by physicians, improvements in nurse staffing, and more effective delivery of ancillary services, which include such things as physical or respiratory therapy, or laboratory tests.

"We believe that perhaps the most pressing need in hospital cost containment is to ensure that within each hospital a mechanism, such as a multi-disciplinary committee, exists, which will be responsible along with hospital administration to define and oversee cost management strategies," Sommers said. "This committee process will act to assure patient care quality."

The W. K. Kellogg Foundation, established in 1930 to "help people help themselves," is one of the largest private philanthropic organizations in the world. The foundation said it has distributed more than $843 million in support of programs in agriculture, education and health in the United States, Latin America and the Caribbean.

STUDY NEEDS MALE VOLUNTEERS

STANFORD—

Healthy sedentary males, less than 155 pounds, and male runners, greater than 175 pounds, are needed to participate in a Stanford University Medical Center study as part of on-going studies examining the relationship between physical training and glucose (blood sugar) utilization.

Participants will be required to spend about four half-days in the Clinical Research Center at Stanford and will receive a free physical examination, including an oral glucose tolerance test, measurement of maximum aerobic capacity, measurement of percent body fat, a fat tissue biopsy, and studies of glucose utilization.

The studies are being conducted under the direction of Dr. Gerald Reaven, professor of medicine.

For more information contact Ken Rodnick, graduate research assistant, weekdays between 8 a.m. and 5 p.m., at (415) 497-6973.

CONCERT WILL BENEFIT STANFORD HOSPITAL MODERNIZATION PROJECT

STANFORD—

A benefit concert for the Stanford University Hospital Modernization Project will be held at Stanford University Memorial Church on Friday, Nov. 22 at 7:30 p.m.

The Truelight Missionary Baptist Church Young Adult Choir of East Palo Alto will sing their versions of "Hold on to God's Unchanging Hand," "My God is Real," "I'm Running for the Lord," and other favorites. The choir has recently traveled to Houston on part of an ecclesiastical tour.

Cost of admission will be $5 for adults and $3 for students, children and senior citizens. Tickets are available at the Personnel Office, Room E009, Stanford University Hospital, 300 Pasteur Drive, Stanford. Tickets will also be sold at the door the night of the concert.

The event is sponsored by the Hospital Modernization Project Employees Steering Committee.

For more information, call Susan Cabral at Employee Relations, (415) 497-6251.

FREE GLUCOSE TESTING OFFERED THE PUBLIC

STANFORD—

Free blood glucose screening will be offered to Stanford employees and members of the public next week by the Medical Center's Diabetic Patient Teaching Committee.

Stanford University Hospital Pharmacist Sandy Bardas said the glucose testing to detect potential signs of diabetes is being offered at an information booth outside the hospital's main cafeteria, 300 Pasteur Drive, from 10 a.m. to 4 p.m., Tuesday, Wednesday and Thursday (Nov. 12-14).

A display, in conjunction with Diabetes Awareness Week, will feature information on understanding and managing diabetes, Bardas said.

For further information, contact Bardas (415) 497-6374.

RADIATION OF LYMPH NODES EXPANDS FROM CANCER TREATMENT ROLE

STANFORD—

Traditionally used for treatment of cancer, high-powered radiation beams have moved beyond the realm of oncology and are now being aimed at serious maladies involving the body's immune system.

Encouraged by the results so far, scientists are optimistic that an experimental therapy known as total lymphoid irradiation (TLI) may revolutionize the way medicine treats many conditions ranging from autoimmune diseases, in which the body attacks itself, to organ transplants. For some people, it may end a life-long requirement for drugs.

A handful of the nation's 2 million arthritis sufferers are already feeling less pain and regaining freedom of movement thanks to TLI. Others suffering from a disease called lupus nephritis are finding relief from this specialized radiation. And kidney transplant patients, who traditionally are put on large amounts of medication to prevent rejection, are shedding dependency on some of the more toxic drugs because of TLI.

"TLI is exciting because it offers the potential to treat more effectively than ever before a variety of diseases that previously would respond only to powerful, toxic drugs with damaging and potentially lethal side effects," says Dr. Samuel Strober, head of Stanford medical center's TLI program.

"Our aim is no drugs, not new drugs for treatment of these diseases. One of the most encouraging things we're learning is that TLI has relatively few severe side effects when applied properly for appropriate conditions."

In the next few years, Strober predicts, victims of multiple sclerosis, thought to be an autoimmune disease, may benefit from TLI. It may also induce permanent immunity, or tolerance, against other diseases. Graft vs. host disease, in which transplanted tissues attack their new owner's body, is another potential target.

TLI is now used for treatment of the immune system at about a dozen research centers around the nation, including Stanford. But the core of its technology is available at any hospital with a linear accelerator. These sophisticated X-ray machines direct moderate doses of radiation selectively at any body area where lymph nodes are located, such as the neck, chest, abdomen or spleen. Neighboring organs are protected with lead shielding.

Dr. Henry Kaplan harnessed the linear accelerator's power nearly 25 years ago at Stanford as a treatment for Hodgkin's disease, a cancer of the lymph nodes. The technique's success at changing Hodgkin's from an almost universally fatal to an almost universally survivable form of cancer is responsible for much of the current interest in TLI for other diseases.

The common factor in Hodgkin's disease and other conditions that can be treated by TLI is the lymphocyte, a type of white blood cell that until recently was thought to be largely inert. But it's now known that these unassuming, microscopic structures are crucial to the body's immune system. Lymphocytes help manufacture antibodies that fight infection. They also kill off and purge the system of cells that have become infected.

more

 The lymphocytes collect in the lymph nodes, where they can be attacked selectively without serious risk to other cells. And that's exactly what TLI does. The radiation is aimed at the lymph nodes and causes a long-lasting drop in the overall number of lymphocytes by damaging DNA, the genetic coding that tells them how to function. Once they're zapped with radiation, the lymphocytes lose their ability to survive or reproduce.

Lymphocytes generally proliferate when the body is attempting to fight infection, which physicians can observe by feeling a swelling in patient's lymph nodes. But when lymphocytes begin to proliferate inappropriately--as in cancer, autoimmune disease or transplant rejection--they can become harmful. Healthy cells as well as diseased cells are destroyed.

Not only does TLI cause a drop in lymphocytes, but as an extra advantage, it creates a predominance of a type of lymphocyte called a suppressor T-cell. These act as the brakes of the immune system, keeping the number of lymphocytes in balance.

In arthritis, lymphocytes collect around the joints in tissue called the synovial membrane. The cluster causes the membrane to become inflamed, which in turn causes pain when the joint is moved. TLI cuts down the number of lymphocytes available to accumulate around the joints.

In recent experiments, 16 of 21 patients with advanced rheumatoid arthritis showed significant improvement after TLI treatment, Strober says. All the patients had previously failed to improve with conventional anti-arthritic drugs.

One grateful TLI recipient is Susan Echenrode, whom physicians diagnosed with rheumatoid arthritis more than 25 years ago when she was 9. Since then, the young woman has undergone more operations than she can remember--at least 15--to relieve excruciating joint pain and make the best use of her arthritic limbs.

About six years ago, her deteriorating condition forced her to stop working as a respiratory therapist at Stanford hospital. "I just couldn't function on my feet all day," she recalls.

Having taxed available therapies to the limit, Echenrode's physician referred her to the then-embryonic TLI program for arthritis sufferers, led by immunologist Strober.

"I had two alternatives: radiation or powerful cell-killing drugs," she says. "Neither one sounded particularly good, but somehow I felt that the radiation might be the best choice."

Today Echenrode says she isn't cured, but "it has lessened the pain." She's back at work at a medical products company office and is even able to enjoy long bike rides on weekends.

Patients usually don't report a decrease in symptoms immediately after treatment, says Stanford's Dr. Richard Hoppe, a radiation therapist who collaborates with Strober on TLI studies. Improvement reaches a maximum level of about 50 percent, based on widely recognized criteria of such arthritic symptoms as joint tenderness, swelling and morning stiffness, and then appears to remain at a plateau after about six months, he explains.

Echenrode, for example, says she felt tired from the radiation treatment and somewhat disappointed, "because after my treatments I wasn't feeling any better." But after several months, she began to feel less pain in spite of the years of previous damage to her joints.

Lupus, an autoimmune disease in which the connective tissue between organs becomes inflamed, is also being attacked with TLI. In another recent study, TLI helped eight of 10 lupus patients who previously had failed to respond to medication. Some of these patients, who had become ill when the lymphocytes proliferated and attacked their kidneys, have shown improvement for nearly four years.

In the case of organ transplant patients, immune disease is induced by the very surgical procedure performed to save the patient's life. Their lymphocytes attack the transplanted organ whose tissues are different from the rest of the body.

Since transplantation became a viable therapy more than three decades ago, powerful drugs have been used to suppress the immune system. These drugs have significant side effects, including damage to the kidneys and skeleton. In addition, they suppress the immune system, leaving the patient vulnerable to a variety of infections.

more

For more than three years, Strober has been collaborating with kidney specialists and surgeons at Pacific Medical Center in San Francisco, using TLI as an immunosuppressive treatment for kidney patients.

Nearly 20 percent of Pacific's kidney transplant patients--about 60 in all--were treated with TLI before their organ transplants, says Dr. Barry Levin, the nephrologist who has worked with the Stanford TLI team. This has eliminated the need for most drugs otherwise required to prevent kidney rejection after the transplant.

"The survival rate of the transplanted kidney, normally about 80 percent after one year, is a little better among our TLI patients," Levin says. The big advantage, he adds, is an improved quality of life.

TLI patients have fewer rejection episodes and spend less time in the hospital recuperating from the infections that may debilitate or even kill many transplant patients treated only with immunosuppressive drugs.

Transplant patients given TLI continue to take small doses of prednisone, a drug mimicking the action of cortisone, a natural body hormone. Efforts to wean patients entirely from prednisone have resulted in rejection of the new organs, Levin says.

Dr. Edward Stinson, a cardiac surgeon who heads Stanford's heart transplant program, says animal studies using TLI indicate "very promising results for cardiac transplantation." Stinson and his team are watching the results of TLI in kidney transplantation before introducing "this exciting new variable" to heart transplants.

But, he says, TLI poses some technical barriers. "Our patients are extremely ill and cannot be supported as readily as kidney patients during the weeks of pre-transplant radiation required," Stinson says. Since donor hearts are scarcer than kidneys--and their availability less certain--patients are not likely to find a heart within a week or two of the end of a finite six-week pre-transplant treatment period. A maintenance dose might be administered until a donor is found, radiologist Hoppe says, but how long a wait is feasible is still a question to be answered.

Strober is optimistic that these barriers can be overcome for heart transplantation. Eventually, he says, with better tissue matching among donor organs and recipients, many powerful drugs used to prevent rejection will be eliminated entirely.

Strober, Hoppe and Levin agree that the side effects from TLI have been minimal for transplant and other patients, consisting of such symptoms as nausea and sore throats. Not a single case of cancer, sometimes a side effect of radiation, has resulted from the new treatment.

While no Hodgkin's patients treated with TLI alone during a 25-year period ever contracted leukemia from radiation treatment alone, Hoppe says, some who received drug or a combination of drug and radiation therapy did contract leukemia.

While the chances of contracting cancer from TLI does exist in theory, Hoppe admits, it's not a major risk for non-cancer patients because the total radiation dose administered to treat arthritis, about 2,000 rads, is low; it's about half the amount administered for Hodgkin's disease.

TLI, as promising as it may be for the small groups of patients that so far have experienced it, should become more exciting as treatment protocols are fine-tuned, Hoppe continues.

"It's not so much a situation where we're talking about TLI vs. drugs. It's a question of getting the right combinations of therapy. We also need to discover the optimum stage of disease for treatment."

So far the deck has been stacked a bit against TLI by nature of its experimental status. Patients ethically can't be put on TLI until other measures have failed.

"It might be significantly more effective if we were able to use TLI first," Hoppe says. "With more experience and confidence in its efficacy and safety, we'll be able to improve constantly," Strober adds.

"It's our firm belief that the long-term toxicity of TLI is less than that of the available drugs," Hoppe concludes, "and that's the main reason for its potential advantage."

CLINICAL ENGINEERS KEEP ALIVE THE MACHINES THAT SUSTAIN PATIENTS

STANFORD—

One of the white-coated men and women grouped around a critically ill patient's life support monitor is most concerned with the machine itself.

The patient's life may depend on this special attention by one of the three engineers or nine biomedical equipment technicians (BMETs) from the Clinical Engineering Department at Stanford University Hospital. The professional team is responsible for making sure that more than 8,000 pieces of assorted equipment used to keep patients alive or monitored are working faultlessly and effectively.

Department Director Steven Friedman notes that the equipment ranges from such headline-grabbing clinical research devices as a partial artificial heart to the life function monitors routinely placed at the bedside of every intensive care patient in the hospital. Even the television sets which boost patient morale pass through the Clinical Engineering Department for a safety inspection before they are sent bedside.

Friedman, who came to Stanford two years ago as department director, notes that a major function is to try to stop problems before they become repairs.

"It's critical that we know for certain that a piece of equipment does in fact do what it is supposed to do," emphasizes Eben Kermit, the engineer in charge of cardiology equipment. His job recently was moved from the Division of Cardiology into the SUH Clinical Engineering Department.

Judy Martin, a biomedical technician in the department, remembers the testing of a hypothermia device which is used to control body temperature of surgery patients during operations.

"The specifications said the device was accurate to within three degrees of the temperature selected," said Martin.

But it wasn't. The machine temperature fluctuated widely—and potentially dangerously. Obviously that equipment never made it upstairs to the operating room after clinical engineering had a close look at what the machine could—and clearly could not—do.

Friedman said that he and his staff consult with physicians, nurses and other members of the health care team to evaluate potential purchases and serve as consultants to a variety of hospital committees. For example, when the hospital was ready to buy bedside TV sets, clinical engineering took a close look at the potential purchases to make sure they were safe and a good value.

Clinical engineering's role is more complex in a university hospital setting, where many devices are new or have been modified—often made more complicated—for special research projects. For example, Clinical Engineering recently spent considerable effort, Friedman said, in inspecting a left ventricular assist device (LVAD) before it was implanted in the first patients by Stanford cardiovascular surgeons.

Some clinical engineering occurs within the hospital on patient units, "and you can believe there is stress when a patient's relative is standing right there with you watching while you make sure that a vital piece of equipment is working properly," said Edward Young, department manager and a BMET.

But much of the time, the engineers and technicians wield soldering irons, screw drivers and their own analytical skills at the bench in the department, located in the hospital's basement.

On a recent afternoon, Martin put down her soldering iron while servicing equipment to talk about her career as a BMET.

"I came to California (from North Carolina 18 months ago) for personal reasons, but before I arrived I applied for a job here at Stanford." She said she was looking forward to the complexities and professionalism which the Stanford clinical engineering department had as far away as her Southeast home.

"Success here is not just doing your job right," said Martin. "Its choosing to do the right thing."

Friedman amplifies that theme:

"There are major differences between what we do here and what is done by an electronics technician in a typical Silicon Valley plant. In the typical industrial setting, each engineer or technician gets to know one or two devices intimately. We don't have the luxury of being able to learn the intricacies of only one or two pieces of equipment. We have a tremendous range of devices, and its vital that we be innovative and effective when problems occur."

Part of the job in this era of cost containment, said Friedman, is knowing when to spend time fixing a piece of equipment and when it is more practical to send the device back to a manufacturer. "That's the sort of judgment our people develop working here," Friedman adds.

Some specialized equipment, such as testing devices in the core clinical labs, come with service contracts from the manufacturer or supplier. In these cases, clinical engineering is not primarily responsible for service. But Young notes that the department's crew sometimes makes quick or emergency repairs as needed on these devices.

In fact, Friedman and Young both say proudly that sometime the manufacturer of a particular piece of equipment will call the department seeking service advice about their own product.

Friedman notes that the department must compete for its work. Departments are free to use outside contractors or services if they choose, but the vast majority of hospital and medical school departments have chosen to use SUH Clinical Engineering, he said.

The work of the technicians and engineers is highly specialized, and an International Certification Commission, now widely recognized in the United States and Canada, examines the technicians and engineers on their knowledge of hospital electronics. Friedman serves on a board which conducts inspections for the organization.

Friedman says two-year colleges have specific programs in biomedical technology, although some of his staff have combined extensive on-the-job training with four-year or more college degree programs in biology, physics, chemistry or an engineering-related field. Martin, for example, has two bachelor's degrees, in biology and medical technology. She began learning biomedical technology when she started fixing the equipment she needed to use for her own work in a chemistry lab.

"A major criterion, beyond a lot of intelligence, is strong analytical skills and the ability to be innovative when problems occur," says Friedman, who has a master's degree in biomedical engineering from New York University.

Before coming to Stanford, he served in a similar capacity at the UC Irvine Medical Center. He has worked in biomedical engineering since 1969 but began his engineering career as an instrumentation engineer helping to design systems for the Boeing 747 jetliner in Seattle.

Kermit, a six-year veteran at Stanford, has a master's in electrical engineering from Sacramento State University.

One of the BMETs, Joe Bennett, is a testament to how the complexities of bioengineering have progressed in the past two decades.

Bennett came to Stanford 12 years ago as a television repairman, "back when the TV was the most complex piece of machinery in the hospital setting," said Friedman. The knowledge proved useful as video monitors began assuming a larger role in the hospital setting and Bennett began training on a variety of more complex equipment as it was added to the patient care inventory.

And Friedman himself began developing an interest in electronics when his father became one of New York City's first television repairmen in the 1940s, "and I began to go with him at the age of 4 when he went out to service the neighborhood televisions."

Friedman now as director doesn't get much opportunity to service televisions or anything else around the hospital. "My hands-on work is confined pretty much to my family. I fix my kids' toys—but only if they fill out a work order first," he jokes.

STANFORD'S MCDEVITT WINS $100,000 AWARD FOR RESEARCH

STANFORD—

Dr. Hugh O. McDevitt, Joseph D. Grant professor of medical microbiology and medicine at Stanford University School of Medicine, has been named the 1985 recipient of the $100,000 Lita Annenberg Hazen Award for excellence in clinical research.

He was presented the award Tuesday, Nov. 5, at The Mount Sinai Medical Center in New York City. The award is made annually by the Mount Sinai School of Medicine.

McDevitt, who will become chairman of Stanford's department of medical microbiology in January, was selected for his work on the genetic control of the immune system. He has been studying immune response genes since the early 1960s and has developed immunological approaches for the clinical treatment of diseases.

The award was established in 1979 by Lita Annenberg Hazen, a philanthropist who has made many contributions to biomedical research. It has the double purpose of honoring established researchers and encouraging young physicians to enter biomedical research. As a result, half of the $100,000 prize goes to a young physician chosen by the award winner to join in current research.

In 1982, the Hazen award went to Drs. Michael Brown and Joseph Goldstein of the University of Texas Health Science Center in Dallas, recipients of the Nobel Prize in Medicine this year. Other recent winners include Dr. Robert J. Lefkowitz of Duke University Medical Center in 1983 and Dr. Yuet Wai Kan of the University of California-San Francisco in 1984.

"We honor Dr. McDevitt for his elegant research, which bridges basic and clinical immunology and which has yielded significant insights into the possible prevention or cure of immunologically mediated disease, and for his excellence as a mentor," Dr. James F. Glenn, president and chief executive officer of the Mount Sinai center and chairman of the award selection committee, said in making the presentation.

The selection committee is made up of nationally recognized scientists who meet each spring at Mount Sinai to choose the recipient from a list of nominees.

McDevitt, 55, was a Stanford undergraduate and received his medical degree from Harvard Medical School. He has been on the Stanford faculty since 1966. He was promoted to professor of medicine in 1972 and received an appointment in the department of medical microbiology in 1978. During the 1970s he headed both the division of immunology in the department of medicine and the clinical immunology laboratory at Stanford University Hospital.

In 1977 he received the Borden Award for outstanding research from the Association of American Medical Colleges and in 1981 he received the Passano Foundation Award for research on "the relationship between the immune system, histocompatibility antigens and human disease."

NEW RESEARCH PROGRAM FOCUSES ON BLOOD TRANSFUSION MEDICINE

STANFORD—

A federally funded specialized center of research in transfusion medicine—one of two in the nation—has been established at Stanford University Medical Center.

The center, funded by more than $3.5 million from the National Institutes of Health for the next five years, will apply the latest advances in molecular biology and immunology to clinical problems associated with blood transfusion, said Dr. Carl Grumet, associate professor of pathology and director of Stanford Medical School's transfusion service.

"There are 15 million blood units transfused annually into approximately two-and-a-half million recipients in the United States," said Grumet, who is the new center's director.

"Most transfusions are safe and effective," he added. "But because of new therapies, such as bone marrow transplantation, and new diseases, such as AIDS, this area of medicine is not moving fast enough. As a result, we are behind in translating basic research progress into clinical benefits."

Three of the center's five major research projects focus on investigations of viruses that can be transmitted through blood transfusion, including cytomegalovirus (CMV), the AIDS (acquired immune deficiency syndrome) virus, and hepatitis viruses. A fourth project involves study of varicella-zoster virus (VZV) infection, and its prevention or treatment by antibodies derived from blood. VZV causes chicken pox and shingles. The fifth project aims at developing better methods for determining tissue compatibility, with particular application to bone marrow transplantation.

CMV infection is the number-one cause of death following bone marrow transplantation, said Grumet. It is also a major problem for susceptible premature infants, with a death rate as high as 1 in 40 for those who are transfused. Researchers will attempt to identify possible vaccine candidates against CMV and better methods for screening against CMV-contaminated blood. They will also be developing better methods for treating post-transfusion CMV infections.

About one percent of the estimated 15,000 AIDS cases in the U.S. are thought to be associated with blood transfusion or blood products. As many as 150,000 people may be carriers of the virus, Grumet said.

The AIDS project in the new center will attempt to develop improved methods for detecting the AIDS-associated virus and preventing transmission of the virus through blood transfusion. The researchers also hope to learn more about the virus' role in causing AIDS, with the ultimate goal of finding possible preventive or treatment methods.

The hepatitis-B virus—although less prevalent today than formerly in donated blood, due to better screening methods—can still be transmitted through transfusion, Grumet said. Researchers in the center are working on a genetically engineered vaccination method which could provide protection against this disease.

11-4-85

-more-

The varicella-zoster project focuses on production of human monoclonal antibodies against the virus. These may help in development of a vaccine, as well as lead to better methods for diagnosing and treating VZV infections.

Development of better methods for typing and matching donors and recipients could help improve results in the 1,500 bone marrow transplants performed annually in the U.S., Grumet said. The researchers are developing monoclonal antibodies and DNA probes to aid in this effort. The monoclonal antibodies could also be useful in suppressing rejection of transplanted tissues as well as in new modes for treating certain autoimmune diseases, such as multiple sclerosis, Grumet said.

A common thread throughout most of these studies is the use of human monoclonal antibodies, Grumet said. A monoclonal antibody facility, headed by Dr. Steven Foung, assistant professor in pathology, is one of the important core elements of the center.

In addition to Grumet and Foung, other Stanford investigators in the center include Dr. Edgar Engleman, associate professor of medicine and pathology, Dr. Rose Payne, emeritus professor of medicine, Dr. Edward Mocarski, assistant professor of medical microbiology, and Dr. William Robinson, professor of medicine.

Although the center is based at Stanford, several other local scientists are participating as investigators, including Dr. Lenore Pereira, associate professor at the University of California, San Francisco (UCSF), Dr. Michael McGrath, assistant professor at UCSF, and Dr. Evelyne Lennette, co-director of Virolab in Emeryville.

TECHNIQUE TO MEASURE TEMPERATURE OF STARS EXPLORED IN MEDICINE

STANFORD—

A new technique to measure body temperature, which would allow doctors to non-invasively treat tumors with heat, has been suggested by Stanford University scientists.

Radioastronomers have used the technique, called microwave radiometry, to record temperatures of stars. Now engineers want to use it to detect the small amount of microwaves emitted by warm, living bodies.

Precise readings of the temperatures within a tumor would aid success of an as yet experimental therapy to kill cancers with heat. The treatment, called hyperthermia, is being tested in combination with radiation at Stanford University Medical Center and other hospitals.

The key to hyperthermia is keeping the tumor tissues evenly warmed to a target temperature a few degrees above body heat. But present methods to monitor and give feedback on heat are invasive, hence the need for alternatives.

"We would like to measure the three-dimensional distribution of temperature within the treated area without having to introduce anything into the body," said Dr. Stavros Prionas, research associate in radiology at Stanford.

In a feasibility study published in the November issue of the journal *Bioelectromagnetics*, Prionas and Dr. George Hahn of the Stanford University School of Medicine outlined the theoretical basis and requirements for microwave radiometry.

Prionas, a cancer biologist with a Masters in engineering, explained in an interview that advances in technology now make it possible to use microwave radiometry to take a tumor's temperature.

Equipment can be cooled to reduce electronic noise that otherwise would mask the minute microwave signals coming from the human body. And, he said, there are new spiral antennas to transmit and receive the microwaves.

He said that the Stanford hyperthermia group intends to develop a microwave applicator that can double as a sensor. The applicator, a palm-sized plate with an embedded spiral antenna, will intermittently scan the temperature of the tumor and nearby healthy tissue as it delivers warming microwaves. Electronic circuits will adjust the amount of microwaves applied, to correct any deviations from the desired temperature and thus keep the tumor evenly heated.

Cost of the instrument as yet is prohibitive for routine clinical use, Prionas said. But he expects the price to come down, he added, as many of the components required to detect microwaves within the human body "are already cheaper than they were a few decades ago."

RCA and a research group in France have already developed devices that can look at one or two frequencies of the microwaves emitted by humans, he added.

12-30-85

more

As the science of medicine becomes more sophisticated, doctors demand more and more of engineering. Since the seventeenth century, a simple glass tube filled with liquid has served to measure body temperature. Now, the need to control heat directed at tumors has rendered the humble thermometer obsolete.

Sampling the temperature at the skin or within a couple of convenient body orifices is fine for monitoring the course of a fever. And surface temperature suffices for physicians who wish to guide hyperthermia treatment of skin cancers.

But to watch over the heat delivered by hyperthermia therapy to deeper tumors, doctors have had to insert temperature probes. This invasive requirement has posed a limit to the hyperthermia approach, according to Stanford researchers.

In hyperthermia therapy, radiologists try to selectively heat and thereby weaken cancerous cells, explained Prionas.

With microwave radiation, tumor cells are taken from normal body temperature of 39 degrees Centigrade, he said, to 43 degrees (109 degrees Fahrenheit, the heat one encounters in a hot tub, or by day in a desert). He added that an hour of this elevated temperature renders the tumors more sensitive to conventional cancer therapies with x-rays or drugs.

The amount of microwave energy used to induce localized hyperthermia (literally, elevated heat) is not enough to char cells the way a microwave oven cooks food, he noted.

Currently, Prionas said, researchers testing hyperthermia in cancer patients can thread fine, temperature-sensing thermistors or thermocouples into tumors to monitor temperature.

These devices, Prionas said, "are very nice indeed, but they only give temperature profiles along the track (of their insertion)."

Conceivably, he said, a number of thermistors or thermocouples could be placed in and around a cancer to get a view of temperatures in three dimensions. But while thermocouple and thermistor wires come as thin as horsehairs, a bristling array would be required for a complete temperature picture, and that would be too invasive, Prionas said.

Even such innovations as fiber optic probes and silicon diodes can take temperatures "at only a few points or along a line," he said; "we want a volume."

So far, his calculations show that microwave radiometry can scan temperature in one dimension. But, he said, an applicator made of a mosaic of smaller spiral antennas could expand the microwave profile into a three-dimensional picture.

He expects the method of microwave radiometry to help doctors treat cancers that generally lie an inch below the skin. Thus many deep tumors will still be beyond the reach of precisely controlled, noninvasive hyperthermia. But, Prionas points out, cancer of the breast and chest wall will be especially amenable to microwave heat therapy.

SHOOTER RECEIVES JAVITS RESEARCH AWARD

STANFORD—

Dr. Eric Shooter, professor and chairman of neurobiology, recently was awarded a $2.7 million seven-year Javits Neuroscience Investigator Award from the National Institutes of Health (NIH).

The award honors former Senator Jacob K. Javits of New York, a victim of amyotrophic lateral sclerosis (a neurological condition also known as Lou Gehrig's disease).

The special Javits awards, mandated by the U.S. Congress, are made by NIH's Institute of Neurological and Communicative Disorders and Stroke to investigators "who have a distinguished record of substantial contributions in some field of neurological or communicative sciences."

Shooter is using the funds to study nerve growth factor, a substance required for proper development of many nerves in the body and brain.

Shooter's Javits award is the second made to a faculty member in Stanford's department of neurobiology, he pointed out. Last year, professor Uel McMahan received a $2 million seven-year Javits Award to study the structure and function of regenerating synapses, the communication junctions between nerve cells.

FATHMAN RECEIVES DEVIL'S BAG RESEARCH GRANT

STANFORD—

Dr. Gary Fathman, associate professor of medicine at Stanford University Medical School, has received a $150,000 three-year Devil's Bag Research Award from the Arthritis Foundation, based in Atlanta.

Fathman is one of five researchers in the country to receive the award, which is named after a racehorse that had been favored to win the 1984 Kentucky Derby until it broke two bones shortly before the race.

Fathman will apply the research award to studies of Lyme arthritis, a form of arthritis that may develop following the bite of a certain tick, called *Ixodes damminni*.

The Devil's Bag Research Award was created from a $600,000 fund donated to the Arthritis Foundation by James Mills of Middleburg, Va., from the syndication of his retired horse.

Other recipients of the award are from Johns Hopkins University School of Medicine, Harvard Medical School, Duke University, and Dartmouth Medical School.

FOR IMMEDIATE RELEASE

NEW ANTI-TYPHOID VACCINE UNDER DEVELOPMENT MAY BE ENGINEERED TO "PIGGYBACK" ALONG IMMUNITY TO OTHER DISEASES

STANFORD—

A "piggyback" vaccine that may be able to immunize against several diseases at once is being developed by Stanford University Medical School scientists.

The vaccine consists of live typhoid fever bacteria—*Salmonella typhi*—which have been genetically disabled so that they can't cause disease.

Supplemented with genetic material to induce immunity against other infections, the enfeebled bacteria some day may be engineered to pack a "five-in-one" wallop, suggested Dr. Bruce Stocker, professor of medical microbiology.

Stocker's laboratory is working with support from Praxis Biologics, a company based in Rochester, New York, to develop and test the anti-typhoid vaccine.

The still-experimental agent may soon undergo trials of its power to prevent typhoid fever in Santiago, Chile, where that illness is common, Stocker said.

Although typhoid fever is now rare in the United States, World Health Organization estimates suggest there are 12 million cases each year worldwide, Stocker said. "With good treatment, the mortality rate is only about one percent," he added. "But where such treatment is not available, the mortality rate is about 10 percent."

An existing anti-typhoid vaccine given by injection is only partially effective, produces some undesirable side effects, and requires yearly boosters, Stocker noted.

The new vaccine is given by mouth and should produce no unpleasant side effects, he added. The vaccine already has passed its initial safety tests in human volunteers at the Vaccine Development Center of the University of Maryland School of Medicine in Baltimore.

Stocker hopes that it will be more effective than another anti-typhoid live vaccine recently developed by a Swiss researcher. That vaccine was highly effective in initial trials in Egyptian schoolchildren but has since performed less well in trials in Chile, he said.

Moreover, by adding optional genetic "accessories," the new vaccine from Stocker's lab could perhaps be engineered to provide immunity against diseases such as malaria, schistosomiasis and hepatitis, he hopes.

One experimental version of the anti-typhoid vaccine already contains an additional gene—engineered into the vaccine by Dr. John Clements of Tulane University Medical School—that may protect against "the commonest sort of traveller's diarrhea," Stocker said.

Tony Nnalue, a graduate student in Stocker's lab, is investigating the possibility of incorporating an anti-malaria component.

And researchers in England are attempting to fortify the vaccine with genes which might enable it to protect against schistosomiasis, one of the undeveloped world's most devastating parasitic diseases for which there is currently no preventive agent, Stocker said.

more

The hoped-for result is that one or two swallows might provide multi-disease immunity as well as protection against typhoid. This would be particularly advantageous for people in the Third World who do not usually have easy or frequent access to medical care.

Others who contributed to the vaccine's development are Stocker's former graduate students, including Susan Hoiseth, Ronald Brown, and Mary Frances Edwards.

Manufacturing the vaccine may be very economical, Stocker said, because harvesting and purification steps aren't needed as they are for many of the new vaccines made through recombinant DNA techniques. "The typhoid bacteria in our vaccine will themselves manufacture the other immunity-inducing proteins, forming a naturally 'packaged' multiple vaccine," he explained.

The vaccine is called "live" because the typhoid bacteria, though crippled, remain alive and harmless inside body tissues. "For some diseases, vaccines made from killed bacteria or viruses just don't work," Stocker explained.

The persistence of the live bacteria gives the body's two systems of immunity time to be recruited into action, he explained. ("Cellular" immunity as well as "humoral" immunity—mediated by antibodies—is thought to be necessary for banishing parasitic diseases from the body.)

Stocker's vaccine work has come to fruition at the culmination of his scientific career.

In 1959, he first thought of the strategy embodied in the new vaccine. However, at that time there was no easy way to genetically cripple bacteria in the required way, he recalled. But developments in bacterial genetics now have made it possible to genetically modify bacteria so that they can't grow unless they are provided with specific growth factors.

Stocker's lab modified the *Salmonella* bacteria so that they require two growth factors—para-aminobenzoic acid and adenine—that are unavailable in human tissues. "Such nutritionally dependent bacteria can easily be grown in the laboratory, but they cannot multiply in human tissues and so cannot cause disease," Stocker said.

However, the bacteria can survive in the person's tissues for several days. "This probably explains the ability of live bacterial vaccines to stimulate a good immune response," he said.

The anti-typhoid vaccine is made from bacteria that are crippled in two different ways, requiring two different growth factors; this provides extra safety, Stocker said.

"Each mutation by itself would probably make the strain harmless, which means that a strain with both mutations can be guaranteed to be safe," he explained. The bacteria have been mutated in such a way that they cannot revert to their original form, he added.

The first strains of the new vaccine were designed to protect cattle from a bovine disease caused by *Salmonella* bacteria. These animal vaccines are now undergoing testing in calves, in Sweden and at the University of California Veterinary School in Davis.

"I think it's quite appropriate that a vaccine using typhoid bacteria has been developed at Stanford," Stocker commented. "The Stanfords founded the university 100 years ago after their 17-year-old son died of typhoid fever in Italy. Stanford University owes its existence to this bacterium."

In addition to Praxis' support, other funding for the vaccine research has come from the National Institutes of Health, the U.S. Army Medical Research and Development Command, and SmithKline-RIT (Belgium).

SHUMWAY PREDICTS INCREASE IN HEART TRANSPLANTS FOR CHILDREN

STANFORD—

Heart transplant operations in the next few years are likely to feature increasing numbers of children, according to Dr. Norman E. Shumway, transplant pioneer and chairman of the Department of Cardiovascular Surgery at Stanford University Medical Center.

Stanford, which has the largest heart-transplant center in the world, has had only a handful of young patients so far. But Shumway said advances in anti-rejection drugs and surgical techniques have dramatically expanded the transplant possibilities for children.

He noted that of the 18 Stanford patients under 18 who have received transplanted hearts, 16 are alive and doing well. "The results seem to be better in the younger age group," he said. "We're very interested in looking into that."

Shumway credited an operation performed by Dr. Philip E. Oyer with changing the thinking at Stanford about transplants in children. In that operation, a grown man received the heart of a 12-year-old boy. When the heart turned out to be much smaller than expected, Oyer was forced to use it as a "piggy-back" heart, supplementing the functions of the man's original heart rather than replacing it.

But the smaller heart grew, eventually taking over the primary heart function for the recipient. "So we know a transplanted heart will grow and develop along with the patient," Shumway said. "That made it feasible to consider heart transplants in younger patients."

Another factor increasing the prospects for transplants in young patients is the development of cyclosporine, an immunosuppressant drug that reduces the chances of a heart being rejected by the body of the recipient. Cyclosporine can be used in smaller doses and has less severe side effects than some of the drugs that were used previously.

But any kind of immunosuppressant poses more problems in a child's body than in an adult's and physicians have to be very careful even with cyclosporine, because large dosages can be toxic.

Heart biopsies, which must be performed regularly to monitor the rejection possibilities, present another unusual hazard in young transplant recipients. The procedure involves inserting a fine wire into the heart, and the risk comes from the fact that the thinner walls of a child's heart are more easily perforated.

However, Shumway said, there are other means of diagnosing possible rejection. "An echocardiogram is one," he said. "It can be done without piercing the skin. And we're looking at other indicators (of rejection)."

One thing that is not as much of a problem as might be expected is finding a donor heart small enough to replace that of a child. That's because most young transplant candidates are suffering from familial cardiomyopathy, in which diseased hearts become very large.

12-17-85

more

"The donor pool is not as restricted as you might think," Shumway said. "We can use teen-age or even young adult hearts."

Of course, there is always a problem in finding enough donors for transplants of any age. Shumway hopes that a new state law, requiring hospitals to ask families for organ donations when a patient dies, will help increase public awareness of the need. He also noted that more and more drivers are carrying donor cards supplied by the Department of Motor Vehicles.

Dr. David Baum, chief of pediatric cardiology, said Stanford receives six to ten inquiries a year about heart transplants for children and two or three transplants are performed annually. He expects the inquiries to increase as people become more aware of the possibility of such transplants.

Stanford's youngest transplant patient to date is Elizabeth Craze, who was 2 1/2 when she received a transplanted heart slightly more than a year ago. She is now back home in Cleveland and thriving; so is her 18-year-old brother, Andrew, who received a heart transplant in 1983.

As those two transplants and the name indicate, familial cardiomyopathy is an inherited condition. Stanford, in fact, has had two other sets of sibling transplants and all four of those patients were suffering from familial cardiomyopathy.

Elizabeth's parents, Susan and Charles Craze, lost three other children to the disease before transplants in children were successful. They are vocal supporters of programs encouraging organ donations.

STANFORD APPROVES NEW ALCOHOL AND DRUG ABUSE PROGRAM

STANFORD—

A new program to treat patients with alcohol and drug dependencies was approved Wednesday, Dec. 11, by Stanford University Hospital's board of directors.

The hospital medical board is expected to approve the medical policies and procedures at its January meeting, and the program is scheduled to get under way by late February.

There will be a 12- to 14-bed unit at Hoover Pavilion to treat patients who require short-term detoxification and stabilization. There will also be a well organized outpatient component that will provide intensive outpatient therapy and continuing care. Patients with significant medical and psychiatric problems will also be cared for, if necessary.

Dr. William Hazle, a psychiatrist, will be medical director of the program and Robert Matano, a psychologist, will be program director. Medical treatment will be supplied by physicians of the Stanford Medical Group and the full range of hospital services will be available to treat acutely ill patients.

The Stanford program is intended to offer a flexibility lacking in many similar programs. Patients will not be hospitalized for a fixed length of time, such as 30 days. The intent is to have them return to their normal routines as quickly as possible, with an emphasis on outpatient treatment.

Surveys indicate there are more than 125,000 people with alcohol and drug problems in San Mateo and Santa Clara counties. Stanford projections estimate the program would handle 383 patients the first year.

Carole Price, hospital associate director who presented the program report to the board, said that at some point patients under 18 might be admitted but there are no plans at present to include adolescents.

In other action, the board:

- Approved the membership of the newly organized academic committee. It will be chaired by Dr. David Korn, dean of the medical school. Members include Dr Peter S. Bing, Dr. Robert Chase, Dr. Robert Cutler, William F. Massy, Dr. William Northway, Mona Cross Sowiski and Geraldine Steinberg. University President Donald Kennedy and hospital Director Sheldon S. King are ex-officio members and Dr. James F. Silverman is the staff member.
- Received word of the appointment to the board of Dr. R. Hewlett Lee, executive director of the Palo Alto Medical Clinic. He replaces Dr. Walter L. Arons.
- Accepted the resignation of board member Nancy Munger.
- Approved an increase in the Hospital Modernization Program fundraising goal from $15 million to $27 million.
- Discussed procedures for the access of community physicians to hospital-based clinical services and approved the granting of access to Drs. Edward Anderson, Bruce McAuley, Hardwin Mead, Matthew Selmon, John Simpson and Roger Winkle.

R. HEWLETT LEE APPOINTED TO STANFORD HOSPITAL BOARD

STANFORD—

Dr. R. Hewlett Lee, executive director of the Palo Alto Medical Clinic, has been appointed to the Stanford University Hospital Board of Directors.

He was named by the general members of the Hospital corporation to replace Dr. Walter L. Arons, a community physician whose term is ending. Arons has been on the board since February, 1981.

Four other members of the hospital board were reappointed: Dr. Lawrence G. Crowley, William F. Massy, Linda Meier and Dean Morton.

All of the appointments are for three-year terms.

The 18-member board sets policy for the hospital. It is comprised of community, medical and lay leaders as well as university faculty and administrators. Twelve of the members are elected by the general members of the Hospital corporation, who are also trustees of the university.

Lee, 59, received both his bachelor's degree and his M.D. from Stanford. He has been a member of the surgical staff at Stanford University Hospital since 1956 and has served on several hospital committees.

He is also chairman of the board of governors, health care division, of the Palo Alto Medical Foundation. He has been president of the Santa Clara County Medical Society and has been appointed to several state commissions, including the Health Care Commission of California and the special advisory committee to the director of health.

ANCIENT SCOURGE OF AFRICAN SLEEPING SICKNESS SLOWLY YIELDING NEW CLUES ABOUT MOLECULAR BASIS OF DISEASE

STANFORD—

A platoon of invaders aims for the heart of the defense system. Wave after wave of attackers are destroyed, but they keep coming back and eventually conquer.

This isn't the latest adventure movie: It's a drama played out in the body of a person with African sleeping sickness.

The invaders are *trypanosomes*, tiny parasites that enter the bloodstream through the bite of the tsetse fly. The defenses that finally give way are those of the body's immune system.

Researchers at Stanford University Medical School are studying the molecular biology of the cunning *trypanosome* to learn more about how the parasite scales the body's immune fortress.

The knowledge could have broad implications for understanding infectious disease at the molecular level. Other organisms, including those that cause gonorrhea and acquired immune deficiency syndrome (AIDS), can also elude the immune defenses.

It could also some day lead to an effective vaccine or drug against sleeping sickness, a disease that helped shape the history of the African continent.

At the turn of the century, says medical microbiologist Dr. John Boothroyd, sleeping sickness terrorized equatorial Africa.

"Even AIDS doesn't compare in terms of the fear," says Boothroyd about the disease that in one epidemic alone killed two-thirds of the population around Lake Victoria.

Symptoms of fever, fatigue, daytime drowsiness and nocturnal insomnia are common, leading to more generalized apathy, convulsions, coma and death when the invading *trypanosomes* reach the spinal cord and brain.

Henry Stanley—of "Dr. Livingstone, I presume?" fame—unwittingly spread the disease as he traveled down the Congo River. Sleeping sickness felled native tribespeople, colonial missionaries and explorers alike. It also decimated livestock herds and beasts of burden.

The scourge was so severe that Belgium and England, holders of African territory, established major centers for studying the disease. The quest for an effective drug spawned the science of chemotherapy, Boothroyd says.

A century later, despite programs to eliminate the tsetse fly, and drugs that can at least partially curb the disease, sleeping sickness still affects much of Africa and kills 10,000 people each year, Boothroyd says.

It also prevents susceptible livestock from grazing throughout large portions of the African continent.

A vaccine could prevent the parasite from gaining a foothold in the body, says Boothroyd. But the search for a vaccine so far has been stymied by the organism's unusual ability to escape destruction by the immune system. Like a criminal with a repertoire of "aliases," the parasite repeatedly switches the make-up of its external protein coat, assuming a new disguise to stay one step ahead of the host's immune response.

It's not surprising that the parasite has developed an ingenious survival strategy, says Boothroyd. It needs to outwit the host's immune defenses because it lives in the bloodstream, which is constantly patrolled by the cells and proteins of the immune system.

When the immune system detects the first wave of invading *trypanosomes*, it unleashes antibodies that recognize distinctive proteins on the parasites' outer surface. The antibodies bind to the parasites, signaling other immune system components to kill the invaders. But a small number of the organisms produce an alternate surface protein that the antibodies are unable to recognize immediately. These survivors swell to large numbers before the immune system can gear up to catch them.

"Each time, it's like a new infection to the body," Boothroyd explains. "*Trypanosomes* have a repertoire of up to 1,000 different surface proteins," he adds.

Scientists are beginning to understand the genetic details of how the organism switches its protein coat. Each time the parasite makes a new protein it must decode a gene, a portion of its DNA.

"It's like a cassette recorder with a library of tapes," Boothroyd explains. The "tapes" are the separate genes, each coding for a slightly varying protein. "The organism takes the new gene and duplicates it, then plugs it into a 'play' slot on the DNA molecule," where it is transcribed into another molecule called messenger RNA.

In trying to understand how this process occurs at the molecular level, Boothroyd, postdoctoral scholar David Campbell, and research assistant Deborah Thornton discovered that *trypanosomes* transcribe their genes discontinuously. Humans and most other organisms transcribe genes in one continuous piece.

This difference suggests one possible approach to fighting the disease, Boothroyd says. Drugs now used to treat sleeping sickness are toxic, he explains, because while they block the metabolic processes of *trypanosomes*, they also disrupt the chemistry of human cells. But since discontinuous transcription is so far known to occur only in the parasite, it could perhaps be derailed by a drug that would not harm humans.

Despite the fact that the *trypanosome*'s varying surface proteins form a moving target that the immune system can't strike, Boothroyd and his colleagues still hope that a vaccine might be possible, because preventing the disease is preferable to treating it with a drug.

"It might be possible to find a way that would knock the parasite out before it switches from fly to human," Boothroyd says. Like a person who needs a different wardrobe when moving from the tropics to the arctic, the parasite needs different sets of enzymes for the different environments—tsetse fly and human—it lives in, he explains.

Graduate student Maurine Hobbs is investigating the differences between the set of enzymes the organism uses in the fly and the new set it substitutes for living in human blood.

Boothroyd's work is funded by the National Institutes of Health, the MacArthur Foundation, and the Burroughs Wellcome Fund.

FOR IMMEDIATE RELEASE

IF MEDICAL SCHOOL IS TO REMAIN COMPETITIVE, FACULTY MUST EXPAND PATIENT BASE, TASK FORCE SAYS

STANFORD—

"In the new health care environment, Stanford University Medical Center cannot continue to achieve its education and research missions with its present specialty emphasis and faculty structure."

This is the conclusion of a special Task Force headed by Duncan E. Govan, professor of surgery. The group was appointed by Dr. David Korn, dean of the School of Medicine, last January to study how Stanford could maintain the patient base it needs for its missions of clinical care, teaching and research.

The medical school should develop "training and education programs compatible with the changing delivery system," the Task Force recommended in its 30-page report. "A major challenge is the development of effective clinical learning opportunities in primary care practice, where an increasing amount of physician activity is likely to occur."

Development of a primary care practice will not only help improve Stanford University Clinic's competitive position in the medical market, but "it is a critical element of medical education," the Task Force stated. "If the school seeks to prepare physicians adequately to meet the health needs of the future, its academic program must reflect current trends, in particular, the shift from inpatient to outpatient care."

Noting that present events are seriously affecting patient referrals from private practice physicians to academic centers, the report predicts that fewer patients will be coming to Stanford unless specific strategies are adopted. The Task Force said it explored various alternatives, from identifying areas of potential cooperation with local physicians on the voluntary faculty to regional arrangements.

"The medical center should continue efforts to enter into contracts with other health care institutions to provide secondary and tertiary services on referral," the task force recommended. "It should develop the capacity to provide the full range of services from primary to specialty care, and open up opportunities for contracting with employers, HMOs, and insurers to provide care at reasonable cost."

To achieve a balanced development of clinical programs, the report stressed, the medical school must examine not only the organization of primary care programs, but the academic standing of all Stanford full-time faculty physicians engaged principally in clinical and teaching activities.

"The Task force considers these to be critical issues," the report said. "They encompass questions of department organization, faculty status, appointment and promotion policies, and compensation of all physicians employed by Stanford to be engaged primarily in clinical teaching."

The issues, the report added, extend to fundamentals regarding the school's missions and objectives and should be addressed by the dean immediately, without in any way impeding implementations of its other recommendations.

In accepting the Task Force report, Dean Korn agreed that school mechanisms for accomplishing clinical objectives have been far from optimal. In the past, we have relied on the so-called "triple-threat person"—faculty who were both excellent clinicians as well as researchers and teachers. "The triple-threat person is fast disappearing," Korn commented.

The dean added that independently of how the school deals with new definitions of the clinical professoriate and criteria for rewarding clinical excellence, he will move quickly to begin implementing some task force recommendations.

12-11-85

more

"If we are going to have a medical school and a hospital, we've got to have patients. That's the bottom line," Korn said.

Forces and trends, the report noted, which require academic centers to revise their strategies include:

- Businesses seeking to control the cost of employee medical benefits through alternatives to hospitalization, elimination of unnecessary services, and larger deductibles and co-insurance.
- Employer-sponsored programs focused on preventing illness.
- Insurance companies and other third-party payers, such as Blue Cross and Blue Shield, changing their historical links to hospitals and doctors through fixed price contracts, and discounts which shift some costs and much of the risk to hospitals, clinics and their physicians.
- Advances in diagnosis and treatment which allow medical services previously rendered by hospitals to be provided at lower cost in outpatient clinics and the doctor's office; also pressures on hospitals to reduce length of stay.

A very significant trend affecting academic centers, the report notes, is the development of Health Maintenance Organizations (HMOs).

California alone has 42 percent of the nation's HMO enrollees, with 36 percent of San Francisco Bay area's population now belonging to an HMO, according to the report. Twenty-five percent of Medicare recipients will belong to HMOs by 1990 while California expects nearly 100 percent participation in MediCal HMOs over the same period.

Price competition, coupled with restrictions in payment methods, have serious consequences for academic programs, the report concludes. Academic centers have multiple missions because they train physicians and do research to develop new treatments. The centers care for very sick patients who require specialized staffs and the most advanced technology, which cost more.

Additional suggestions for the future have been incorporated in the Task Force report from its subcommittee on an expanded patient base, chaired by Dr. Halsted Holman, professor of medicine.

The group said special centers for intensive care of premature infants, cancer, arthritis, geriatrics, adolescent psychiatry and health improvement should increase cooperation by developing regional arrangements with other health service agencies and professionals for referral of patients.

The subcommittee also recommended:

- Stepped up efforts to achieve an integrated group practice to allow Stanford clinic units to achieve more efficient and satisfying operations for patients and staff.
- Improving services to patients such as expanding clinic hours to evenings and weekends.
- Shortened waiting hours for patients by improving timing of appointments and responses from laboratories.
- A prompt response system for communicating with physicians referring patients to Stanford.

"Their realization would serve to expand and stabilize the patient base for activities at the medical center and medical school, and to initiate a new era in health services for central California, one characterized by cooperation among health care providers, their institutions and the general community," the report said.

Stanford University Clinic averages 140,000 patient visits a year. About 55 percent of the patients come from the Santa Clara and San Mateo Counties, and 45 percent from outside the two counties. More than 65 percent of the patients make their own decision to seek care at Stanford clinic, while the rest are referred by their own doctors.

FORMER STANFORD PROFESSOR CREATES IMAGINARY ZOO FOR CHILDREN

STANFORD—

With this month's publication of a trilogy of children's books, Dr. Jon Eisenson isn't sure whether he's launched a new career—or just picked up an old one.

Stanford University's professor emeritus of hearing and speech science began his career as an English teacher, "And I don't think I've ever gotten over it," he chuckled.

My Special Zoo, illustrated rhyming verse written just for fun, is a radical departure from the long list of scholarly publications already to Eisenson's credit.

The three-book series may have some roots in his work as a neuropsychologist and psycholinguist, but Eisenson insists that, "once begun, the books took on a life of their own."

Although Eisenson is known for working with children and adults with learning and language problems, *My Special Zoo* is appropriate for any child age 3 to 8, he said. Cassette tapes accompany the books for enjoyment and as a learning tool.

Creating the zoo and its imaginary creatures was not a solo effort, Eisenson admits—considerable inspiration came from his grandchildren, then three and six years old.

Even producing the book was a collaborative effort, he said. His sister, Lena Koblentz illustrated the works and family friend Charles Graen composed the tape's musical scores.

Plans for a sequel are already on the boards, he said. "Other animals are waiting in the wings, ready to populate the zoo."

Published by Modern Education Corporation (MEC) of Tulsa, OK, Eisenson's books are available locally and from the publisher.

A former head of the Institute for Childhood Aphasia, Eisenson retired from Stanford University School of Medicine in 1973 and has continued to work with dyslexic children and children with severe language delay.

PSYCHOLOGY AND PAIN LINKS SOUGHT IN CANCER STUDIES

STANFORD—

Self-hypnosis and psychological support groups which help patients master anxiety can be effective ways to control cancer pain, says a Stanford researcher.

Now Dr. David Spiegel, associate professor of psychiatry, is seeking volunteers to expand on the results of previous studies to further test the apparent link between psychological factors and cancer pain.

Research has shown that pain is widespread among cancer patients. For example, he said studies have shown that between 60 and 80 percent of patients whose cancer has spread from its initial point suffer substantial pain. But Spiegel added that comparatively little research has been done on how to relieve pain.

Spiegel wrote about the benefits of hypnosis in pain control in the July/August issue of *Cancer Journal for Clinicians*:

"Pain control techniques employing hypnosis are simple and effective, easy to learn and teach patients, and applicable to approximately two thirds of cancer patients in pain.

"They can be a helpful adjunct to treatment in controlling pain, reducing dependence on analgesic medication, and giving patients a greater sense of mastery over their illness," the study concluded.

In an earlier five-year study of 86 women with breast cancer, Spiegel and colleagues were able to demonstrate that weekly group support and training in self-hypnosis resulted in the elimination of half of the pain experienced by the patients.

"We found that it was the psychological factors—the anxiety and depression and the patients' belief that the pain indicated a worsening of the illness—that were most strongly related to the amount of pain they experienced," Spiegel said recently.

The women in the study all had metastatic breast cancer, meaning that it had spread to another location. Colleagues in the project, conducted from 1977 to 1982, included Dr. Irvin Yalom, professor of psychiatry at Stanford; and Dr. Joan Bloom of University of California at Berkeley.

12-10-85

more

These studies have lead to the need for more research, and Spiegel is looking for about 100 cancer patients to help with the new project.

Spiegel, who will serve as principal investigator for the two-year project funded by the American Cancer Society, said the patients will help investigators understand whether such disorders as anxiety and depression are significantly higher among high-pain than among low-pain patients.

Spiegel predicted that cancer patients who have a great deal of pain will be much more anxious and depressed than people with a little pain.

"We want to learn more about what makes pain better or worse for the cancer patient so that we can help patients manage their pain more effectively," said Spiegel, who directs Stanford's outpatient psychiatry clinic.

In the current study, all volunteers will receive at no cost to themselves a complete psychological evaluation. Half the volunteers, said Susan H. Sands, Ph.D., research psychologist, will receive specific treatment for pain, including self-hypnosis and biofeedback techniques, as well as more traditional treatments such as antidepressants, antianxiety medications and individual psychotherapy.

The researchers will compare measures of pain, mood disturbance, and social support among the treatment and control patients at intervals of one, three, and six months.

For further information, to volunteer, or to refer a patient, contact Sands at (415) 497-6341. Sands said volunteers might need to make several trips to Stanford Medical Center, although patients requiring bedside or home visits by the researchers will be accommodated.

STANFORD OFFERS POST-HOLIDAY WEIGHT LOSS COURSES

STANFORD—

Two post-holiday courses on weight management led by registered dietitians will be offered by the Stanford University Hospital's department of dietetics.

One course, the "Shapedown Program," is intended to help teenagers take charge of their own weight management by combining diet, exercise and behavioral techniques, said clinical nutritionist Kristine Birge.

Classes for this course are scheduled from 4 to 5:30 p.m., Wednesdays, Jan. 29 through April 23. Parent sessions have been scheduled at 7:30 p.m., Feb. 26 and March 26. The registration deadline is Jan. 10.

An adult course, "An Enlightening Experience," includes a personalized weight loss plan, low calorie cooking demonstrations and recipes, menu planning and tips on dining out wisely, explained Birge. Guest speakers in the program will discuss stress reduction, behavior modification techniques and exercise, she said.

Participants for the adult course may register for either afternoon or evening sessions. Evening classes will meet from 7:30 to 10 p.m., Tuesdays, Jan. 15 to March 11. Afternoon classes will meet from 1 to 3:30 p.m., Thursdays, Jan. 16 through March 13.

Enrollment for each of the adult sessions is limited to 20 participants. The registration deadline is Dec. 31.

There is a fee for both courses to be held in the hospital.

For further information on either course, call (415) 497-5432.

STANFORD STARTS WEIGHT LOSS PROGRAM FOR SERIOUSLY OBESE

STANFORD—

A new weight loss program designed to treat patients with serious obesity problems is being started by the Stanford University Behavioral Medicine Clinic in collaboration with the Stanford Medical Group.

Serious obesity, according to the physicians running the program, means that patients will be at least 40 pounds overweight. More likely candidates for the program will be people who need to lose as much as 100 to 150 pounds.

The program is being planned by Dr. Bruce Arnow, clinical director of the Behavioral Medicine Clinic, and Dr. Robert Berkowitz, medical director of the weight loss program. They will operate in conjunction with Dr. Michael Jacobs, director of the Stanford Medical Group.

Berkowitz said the program involves a combination of fasting—in conjunction with a nutritional supplement—behavior therapy and nutritional counseling.

Those accepted into the program, he said, will go without food for 12 to 16 weeks, subsisting on the formula that provides all the basic nutrients. The amount of the formula taken by most patients will average slightly more than 400 calories a day.

Berkowitz and Arnow both emphasized that patients will be under close medical supervision by physicians of the medical group throughout the program to make sure there are no medical complications.

Fasting is just the start of the program. Arnow said that it also involves essential life-style changes. Patients will receive nutritional training and help in changing their eating habits. They also will be encouraged to set up programs of regular exercise.

Obesity is a dangerous medical condition. As Berkowitz pointed out, it contributes to hypertension, adult onset diabetes, heart disease, orthopedic problems and increased risk during surgery.

Berkowitz said the patients will attend weekly meetings and lectures while they are fasting. After they complete the initial part of the program, there will be weekly or bi-weekly meetings for a year to reinforce the life-style changes.

Similar programs have been tried in other parts of the country in recent years, Berkowitz said, and 80 percent of the patients have managed to lose at least 40 pounds.

Arnow and Berkowitz both made it clear that a fasting program is not appropriate for all severely obese persons. Those who have medical problems that might be aggravated by fasting will be referred to other programs.

The Stanford program will start in January. An orientation meeting is scheduled Dec. 17. Information on the meeting or the program is available by calling (415) 497-5065, from 9 a.m. to 5 p.m., Monday through Friday.

HOME HEALTH CARE SERVICES GROWING AT EXCEPTIONAL RATE

STANFORD—

The health care facility that seems to be showing the greatest increase in use during the 1980s isn't the hospital, the clinic or the convalescent hospital—it's the home.

According to Kathryn Janz, director of the Stanford University Hospital Home Care Program, there are now 5,000 home health care agencies in the United States. In the last 15 months, she said, such agencies have increased by 23 percent and there has been an astounding increase of 250 percent in the number of hospital-based agencies.

But Janz, a veteran of home care agencies in New York, Chicago and San Francisco who started the Stanford program earlier this year, finds the increase in the type of home nursing services just as impressive. And she credits the competition from growing numbers of agencies with bringing about that change.

"In the last five years, the types of services we do in the home have increased dramatically," she said. "Agencies have learned they have to offer a much wider range of services to keep up with the competition and they've greatly increased their availability and accessibility."

Janz surveyed the accomplishments of the Stanford program as health care agencies across the country took note of Home Health Care Week, celebrated from Dec. 1 through Dec. 7 this year.

In the seven months since Stanford's program started in May, she said, nurses have made approximately 6,000 home visits. Most of the visits have been to elderly patients, as is typical in home care services, but there are patients in a variety of categories.

For example, 7 to 10 percent of the cases involve pediatric or pre-natal care. One infant in particular had been in the hospital for almost a year, with a lot of serious problems, and would probably still be hospitalized if it weren't for home care.

"We took that baby home," Janz said, "utilizing the pediatric nurses that were in the hospital. It was really a joint effort between the hospital, the nurses and home care. We've had him for almost six months now and he's doing fine ... The doctor says he would never have sent that baby home if we weren't here."

To Barbara Burgess, clinical nursing coordinator of the home care program, that kind of a situation is a concrete example of the extra benefits of the Stanford program because it can draw on the specialized knowledge available through the hospital.

"We're providing a service that clearly was not provided before," she said, "because we can use the specialty nurses in the hospital. We're part of Stanford."

The nurses in the home care program have the same contract and the same standards as those in the hospital. Besides Janz and Burgess, there are six registered nurses, two relief nurses who work both in home care and in the hospital, three aides, three physical therapists, three occupational therapists and one social worker. Home care also uses other aides from the hospital and has a contract with a speech and language therapist.

Burgess noted that nurses are on call at all times. "We have full seven-day-a-week services so that we can provide aides, nurses and other services," she said.

"When I was staffing the program," Janz said, "I made a conscious decision to provide as many full-time people as possible so we would be able to have continuity. The patients have a really close relationship with one particular nurse and therapist. Either the nurse or the therapist acts like a case manager and coordinates all the other services."

Stanford's home care program is based in the Lytton Gardens Nursing Home at 437 Webster St., Palo Alto, in the heart of an area of elderly persons likely to need such help. However, the program covers a much wider area, serving Alameda County as well as San Mateo and Santa Clara counties.

"We started the first week with two counties," Janz said, "then found there were a lot of patients in Alameda County that really needed our services. ... We can provide very high tech care to those patients who have a more difficult time."

Janz expects the Stanford service to keep growing for many of the same reasons home care across the country is growing: Length of stay in hospitals is decreasing, there is an increase in the numbers of elderly who are likely to need home care, and the costs are less than other types of care.

In addition, there is a special benefit cherished by many elderly people and their families—independence. Most patients want to decide how and where they will live, Janz said, and welcome the fact that "home care is focused on short-term, get-in-get-out care that teaches the patient how to be as independent as possible."

Some patients also want to determine how and where they will die, she added, noting that home care makes it possible for some terminally ill patients to die at home. "Death at home is a much bigger option now than it was," she said.

Regardless of the degree of illness, Janz said, most patients want to avoid institutionalization and home care can often help them achieve that goal. Home care, she said, has "a much higher well-discharge rate" than nursing homes, which often do not stress having a patient become independent.

"When you walk in the door of a nursing home," she said, "there's a back door to leave. But it's a narrower door than the one you walk into."

Obviously, she said, some people must be institutionalized, particularly if they are mentally confused. But, she added, "people who have multiple problems from a clinical and medical point of view but are alert can stay at home with home care services."

Those services involve treatment as specialized as chemotherapy and visits as frequent as three or four times a day. The average number of visits per patient is 12-14, Janz said, and the goal is always to make patients independent as soon as possible.

Stanford physicians as well as the patients welcome the home care services. Dr. Michael Jacobs, medical director of home care services and director of the Stanford Medical Group, said that having nurses go into homes and assume patient care "has made our lives much easier. They've done an outstanding job."

STANFORD APPROVED FOR SANTA CLARA COUNTY TRAUMA CENTER

STANFORD—

Stanford University Hospital won approval from a review committee Monday to become one of three trauma centers for Santa Clara County.

County and hospital officials now will begin negotiating a trauma center contract, which must be approved by the county Board of Supervisors. Contracts are also being negotiated with Valley Medical Center and San Jose Hospital, the other two sites approved as trauma centers. The three centers will treat the county's critically injured patients, estimated at 1,300 a year.

Monday's visit was the second to Stanford by a site review committee. It was necessary because on the first visit, in September, the committee found problems that were largely the result of inadequate time for Stanford to organize its trauma center presentation.

"This (trauma center) represents a shifting of the hospital to be more clinically and patient oriented," said Dr. Michael Eliastam, the hospital administrator coordinating the program. "It also represents our orientation to our local community and to the greater region."

Milton Silberberg, the county's emergency medical services administrator and a member of the review committee, said he was "delighted" that Stanford was approved and said the hospital "absolutely" cleared up any questions that were brought up at the first site visit.

Eliastam said Stanford officials felt it was "just a question of time to get (the trauma system) up and operating in a complex institution such as this."

On the second visit, he said, "we were able to clarify how the system works at Stanford and specifically that the trauma service is part of the surgery service and is operated by the surgery service."

MYSTERY OF HEART FAILURE YIELDING TO RESEARCH

STANFORD—

While heart transplants make headlines, Stanford University medical scientists search for defects that make the heart muscle fail.

Processes that cause heart tissue to deteriorate are still a medical mystery. Today that mystery can be solved only by replacing the dying organ, a heroic maneuver that grabs attention. Far less fanfare has greeted some important spinoffs from the surgery.

"Transplant programs are generating unique research material—human hearts—which we can study to understand more about the disease," said Dr. Michael Fowler, physician specialist at Stanford's Center for Cardiovascular Research.

Already, the work has "produced some profound findings," he said in an interview, and may explain a new, paradoxical therapy that aims to sedate rather than stimulate the weakening pump.

Studies of discarded hearts from transplant recipients show that the muscle is less sensitive to stimulating hormones. This finding may change scientists' views on treatment for the disease of heart muscle called cardiomyopathy, according to Stanford researchers.

"Cardiac stimulants were thought to help," Fowler said, "but our results show that it may be detrimental to flog a failing heart."

The membranes of cells in failed hearts contain a decreased number of the receptors that read hormone messages, according to experiments done three years ago at Stanford by cardiologist Dr. Michael Bristow, who is now at the University of Utah.

Hormones released by nerves and the adrenal glands during exercise or stress tell the heart to pump harder, Fowler explained. But in the diseased hearts there are fewer receptors to transmit the command into the muscle cells.

With this clue to the underlying disorder, doctors can begin to devise new strategies to deal with cardiomyopathy, a progressive disintegration of heart muscle that so far can be slowed, but not stopped.

"We haven't solved cardiomyopathy," Fowler said.

Yet the missing receptors "give us a marker that we can measure to study different drugs or to look at the natural course of the disease," said another member of the Stanford team, physician specialist Dr. Robert Ginsburg.

By studying the worn-out organs taken from transplant recipients, researchers have uncovered some details of the hearts' demise. They find that a particular subset of the receptors on the cell membrane, called beta-1, are lost as the heart muscle fails.

Beta-1 receptors can be stimulated by certain drugs, and a healthy heart pumps more vigorously in their presence. These medications elicit weaker contractions in hearts obtained from transplant patients, reported cardiologists from Stanford and the University of Utah at the annual meeting of the American Heart Association earlier this month.

Failed hearts could still respond to agents that act at beta-2 receptors to increase the heart's pumping force, the researchers found, as beta-2 receptors are still present on the cell membranes.

These results suggest that beta-1 stimulants will not help cardiomyopathy patients. But even stimulants that act at the beta-2 receptors would probably be of no benefit because they may exert other, undesirable effects on the heart, Fowler said.

"Increasing evidence suggests that beta-adrenergic stimulation has its down side," he said. He explained that giving drugs to stimulate the receptors may actually further decrease their numbers.

Data on the loss of beta receptors in heart failure have reawakened interest in treating cardiomyopathy with beta blockers, Fowler said. By chance, Swedish doctors a decade ago noted that beta blockers helped some patients with diseased heart muscle.

Beta blockers are drugs that prevent hormones from binding onto, and activating, the receptors in the heart that regulate its pumping.

In collaboration with Swedish colleagues, American physicians have performed pilot studies with the beta blocker called metoprolol, Fowler said. He added that cardiologists hope to begin multi-center trials of the drug.

With beta blockers, Ginsburg said, doctors may be able to interrupt the underlying pathology of the disease by prodding the heart to make new beta receptors.

"You only partially block the receptors (with the drug)," he explained, "so you allow protein resynthesis and regeneration, yet you still are permitting the receptors to respond."

Fowler cautioned that doctors as yet have no idea if the approach will be better than existing treatments.

"We have to be careful not to raise false hopes," he said.

Currently, the best way to treat heart failure is with vasodilators, which ease the strain on the heart by opening blood vessels, and with diuretics, which flush the body of excess fluid, according to Ginsburg.

Many patients with cardiomyopathy can live with their condition for three to five years if they are carefully monitored and their medication is properly controlled, Ginsburg said. But in some people, the heart becomes unresponsive to drug treatments, he said, and a transplant becomes the only "viable alternative."

"If you could solve why the heart fails, it would make heart transplants obsolete," he added. "It probably won't happen in our lifetime, but that would be the ultimate goal."

SCIENTISTS FIND A WAY TO SWITCH "IDENTITIES" OF SPECIALIZED CELLS

STANFORD—

In basic research with broad implications for understanding development of living things, Stanford Medical School scientists have converted human liver—and other—cells into muscle cells by manipulating signals that control their genetic material, DNA.

The feat is one of the first convincing demonstrations that cells destined for one specialized fate can switch to another, said Dr. Helen Blau, assistant professor of pharmacology and head of the research team.

The finding contradicts previous notions that specialized cells have a fixed and irreversible pattern of gene expression, she added.

In the laboratory, Blau and her colleagues succeeded in reprogramming DNA from human liver, lung, skin, and cartilage cells so that it functions more like the DNA in muscle cells.

The ability to change the functional characteristics of cells provides scientists with a new tool to study such diseases as cancer, developmental afflictions such as muscular dystrophy, and to develop more effective strategies for gene therapy.

The work was reported in the November 15 *Science* magazine special "Frontiers in Biology" issue devoted to research areas that have "great potential for the future," according to an editorial written by Dr. Daniel Koshland, Jr..

Blau's coauthors on the article are Grace Pavlath, Edna Hardeman, Choy-Pik Chiu, Laura Silberstein, Steven Webster, Steven Miller, and Cecelia Webster.

The experiments reported by the Stanford researchers establish a new way to study the genetic basis of differentiation, the process by which cells descended from a single fertilized egg become highly specialized to perform different functions, Blau said in an interview.

All the millions of cells in an individual's body contain the same genetic information in their DNA. Yet, as cells develop into specialized organs, they use different portions of the genetic code.

Skin cells, for example, make certain proteins found only in the skin, while muscle cells produce proteins involved in muscle contraction. Each cell type activates a different set of genes in the DNA in order to produce the proteins it needs to carry out its particular role.

Scientists understand very little about how cells activate or suppress different sets of genes. It's one of the most intriguing unsolved puzzles of biology, Blau said.

The Stanford scientists fused two different kinds of cells—human and mouse—to create a hybrid cell called a heterokaryon. In each case, they fused a mouse muscle cell with a human cell specialized for a non-muscle function such as skin, lung, or liver.

The result was that quiescent muscle-specific genes in the human non-muscle cells became active, producing proteins that are characteristically found only in specialized muscle cells, Blau said.

"I think this technique affords us a unique opportunity to isolate regulators of gene expression, to learn how they interact with specific genes, and to determine how they control the time sequence of differentiation," she said.

Although Blau stressed the basic nature of her laboratory's research, she acknowledged that understanding differentiation is important in cancer research, in successful genetic engineering, and for future attempts at using gene therapy to treat disease.

"Anything that tells us about normal gene regulation and differentiation also can tell us about when regulation goes awry, such as in cancer," she noted.

"In the genetic engineering industry, one wants to make a lot of a particular product. If that is a tissue-specific product, then you have to understand the regulation of tissue-specific genes," she explained.

"In gene therapy, the idea is to try to replace a gene in a tissue where it's aberrant or absent," she continued. "In order to do that properly, you have to know how the gene is regulated."

Blau and her colleagues are using heterokaryons to study how muscle cells differentiate, she noted, which could be important in understanding more about muscular dystrophies, diseases of muscle development.

Blau said that one other possible use of heterokaryons would be in prenatal diagnosis of certain diseases. By fusing undifferentiated amniotic cells with differentiated cells, she pointed out, it might be possible to reveal tissue-specific abnormalities that would otherwise be undetected until later.

The Stanford researchers tested the ability of a variety of different types of non-muscle cells to activate their muscle genes when fused with mouse muscle cells. They found that both adult and fetal skin cells could be activated so "aging does not seem to make a difference," Blau noted.

In addition, they found that cells more closely related to muscle—derived from similar tissue in the fetus—consistently expressed their muscle genes sooner and at a higher frequency than cells less similar to muscle.

They also found that muscle genes could not be activated in one type of cancer cell they tested, unless the cells were first treated with a drug called 5-azacytidine that changed the chemical composition of the DNA.

"It's intriguing that the one abnormal cell couldn't activate its muscle genes in the way that the seven types of normal cells could," Blau said. "It makes even more dramatic the point that cells specialized to be liver, cartilage, or skin, all can be changed into muscle by fusion. That was very surprising."

She also noted that they had established that DNA replication is not necessary for previously silent muscle genes to become active.

The researchers believe that activation of muscle genes is mediated by regulatory molecules that are produced by the mouse cell, transported through the cytoplasm of the hybrid cell and gain access to the human nucleus. (A nucleus is the part of the cell that contains its DNA.)

Isolation of the genes encoding the regulators responsible for muscle gene activation should now be possible, the researchers concluded.

So far, Blau and her colleagues have studied only the activation of muscle genes using heterokaryons, but she believes that "stable heterokaryons could be achieved with cell types other than muscle."

The research was supported by grants from the National Institutes of Health, the Muscular Dystrophy Association of America, the March of Dimes Foundation, and the National Science Foundation.

FOR IMMEDIATE RELEASE

STUDY SCRUTINIZES COST OF REPRODUCTIVE HEALTH CARE

STANFORD—

Only a small portion of the American health care dollar is spent on reproduction-related care, says a report published today (Jan. 3) in the Journal of the American Medical Association.

Obstetrical care, infant care, contraception, abortion and infertility services accounted for about 5.5 percent of the nation's total outlay for health care in 1982, according to Dr. Victor R. Fuchs, professor of economics at Stanford and research associate at the National Bureau of Economic Research (NBER), and Leslie Perreault, a research assistant at the NBER.

"Expenditures for Reproduction-Related Health Care" is one of the first studies to document information about these services from an economic perspective. Controversy over high-tech obstetrical methods and costly intensive care for newborns, and lack of data on other expenditures sparked the study, the researchers indicated.

All figures in the study are based on 1982 prices and quantities. Approximately $17.8 billion of the nation's $322 billion total health care spending went to reproduction-related health care that year.

Obstetrical and infant care were the heftiest portions of this health care sector; the two consumed 46 and 37 percent of the total, respectively. Contraception accounted for 13 percent, abortion took up 3 percent and infertility services amounted to the remaining 1 percent, the researchers found.

The authors caution that these figures and ratios cannot be projected with certainty into the future, since spending for reproduction-related health care is affected by varying factors: the number of women of childbearing age, changes in medical technology, alterations in economic conditions, and certain social and legal considerations.

About 55 million American women are of childbearing age (15-44), approximately 30 million of whom use some form of contraception, including sterilization. An estimated 10 percent of the total have difficulty in conceiving; one million couples seek medical advice or treatment for infertility each year.

Of the six million pregnancies documented annually, 25 percent end with an induced abortion and another 15 percent end in miscarriage or stillbirth. More than 3.6 million babies are delivered in this country, and about 40,000 die within a year of birth.

The researchers estimate that hospital charges account for more than half of the average $2,230 bill per live birth; physicians fees take up 35 percent, and laboratory tests and other procedures make up the remainder. Almost all—99 percent—of babies born in 1982 were delivered by physicians in hospitals or other medical facilities.

About 5 percent of all newborns need intensive care. Many of these children are normal weight babies born with congenital defects; others are low birth weight babies who weigh 5 ½ pounds or less.

Low birth weight babies comprise about 7 percent of all newborns, but they account for more than half of all infant deaths and three-fourths of all deaths within the first 28 days after birth.

1-2-86

more

Teen-aged and unmarried women are more likely than most to bear low birth weight infants.

Because there are no national data on the use of intensive care by newborns, the authors drew their data from clinical studies. These studies indicated that medical care for tiny babies—those weighing 1 to 2 pounds—was far costlier than that for babies who weighed at least 5 ½ pounds. Costs averaged about $19,000 for the tiny infants and about $5,600 for the larger.

Low birth weight babies also are more likely to be put back into the hospital during their first year.

Despite commonly held beliefs to the contrary, these children use only a small part of the total health care dollar, the authors stress. An insurance mechanism that would spread the cost of high-tech baby care over all infants delivered yearly would add between 5 and 10 percent to the total cost per live birth, they contend.

For the 54 percent of American women who are avoiding pregnancy, most rely on male or female sterilization (33 percent), birth control pills (28 percent), or intra-uterine devices (7 percent). Over the last decade, sterilization has overtaken the pill as the most popular form of birth control. Women younger than 30, however, still prefer oral contraceptives.

Barrier methods such as the diaphragm, condom and spermicidal foam account for 23 percent of those who use contraception; 9 percent rely on the rhythm method or withdrawl. About 4 million sexually active women use no form of contraception, although they are not seeking to conceive.

Costs of contraception vary among the different methods. The authors figured the total annual cost of various forms of contraception as follows: $130 for the pill; $111 for the diaphragm; $106 for female sterilization; $47 for the IUD; $30 for the condom; and $22 for male sterilization.

In their comparison, the authors took into acount the timing of payments for contraception. Surgical sterilization is a one-time expense, they noted, but pills and devices must be purchased repeatedly.

The one-time payment for surgical sterilization averaged $1,180 for tubal ligation and $241 for vasectomy; the first-year expenditures for the IUD, diaphragm and pill averaged $154, including the cost of a physician visit and the expense of the device itself.

Average expenditure in 1982 was $81 for each woman who used contraception.

Data indicate that nearly 3 percent of all women aged 15 to 44 had an abortion in 1982; each of the 1.5 million procedures cost approximately $307. Publicly funded abortions (210,00 in fiscal year 1982) cost slightly more at an average cost of $322, the study revealed.

Most abortions (82 percent) are performed in clinics and doctors' offices; the remainder take place in hospitals. Approximately 90 percent of abortions are performed in the first three months of pregnancy and 10 percent in the second three months.

Of the 10 percent of women of childbearing age who have difficulty conceiving, the study determined that most spend little or nothing for infertility problems. A few spend a great deal. In 1982, for example, in vitro fertilization—the so-called "test-tube" procedure—cost about $3,000 for medical expenses for each attempt. Only 15 percent of couples using this technique succeeded in having a live birth.

About half of infertility is partly or completely attributable to a problem in the male partner. As a result, about 10,000 couples turn to artificial insemination each year. If insurers paid for infertility services, more couples might seek counseling and procedures, according to Fuchs and Perreault. The authors estimated that 1 million couples sought counseling and that each spent an average of $200.

Expenditures for each woman of childbearing age averaged $329 per year, although amounts varied greatly between age groups and individuals, the researchers discovered. Women aged 20-30, for example, incurred far more reproduction-related expenses than women aged 35-45. The total average amount spent on reproductive-related care is relatively low, they point out, comparing it with the average of $4,000 spent on persons 65 and over in the same year.

STANFORD TO START KIDNEY, BONE MARROW TRANSPLANTS

STANFORD—

Stanford University Medical Center, the world's leading heart and heart-lung transplant center, is on the verge of starting kidney and bone marrow transplantations.

The executive committee of the School of Medicine gave formal approval Dec. 20 to the report of a task force preparing for the expansion of transplantation activity at Stanford.

Dr. Stanley Schrier, professor of medicine (hematology) and vice chairman of the task force, told the committee that Stanford could have both kidney and bone marrow transplant procedures set up sometime in 1986.

"We've been recruiting in renal transplantation for a year," he said in an interview. Stanford plans to have a three-member team, two transplant surgeons and a nephrologist, but Schrier said the program could get under way as soon as the first surgeon is hired.

Kidney transplants, he said, are "much less invasive" than bone marrow transplants and because they don't require as much in the way of back-up and follow-up medical procedures, are "much easier to set up in terms of specialty services."

Nevertheless, Schrier said, "the bone marrow program is about to take off" and may be in operation before the kidney program.

That's because a pediatric hematologist/oncologist on the Stanford faculty, Dr. Michael Amylon, assistant professor of pediatrics, is already undergoing additional training at the University of Washington in Seattle, a pioneer in bone marrow transplantation.

Stanford intends to do about 100 kidney transplants a year, which Schrier characterized as the number "necessary to meet the needs of clinical research." He stressed the research aspects of the program, saying "our best people tell us that we need that many cases to get reliable answers (to research questions)."

Bone marrow transplantation, used increasingly to treat certain forms of leukemia and other blood diseases, probably would involve only 20 patients a year at first and gradually be extended to 40 or 50. The first transplants, Schrier said, will probably be performed on children.

Schrier estimated that kidney transplantation, which costs about $30,000 per operation, would be financially self-supporting if Stanford had 100 cases a year. Bone marrow transplantation, which costs about $100,000, would need 40 to 50 cases a year to reach the break-even point.

Finding patients is not expected to be a major problem. The task force report noted that in 1984 Stanford referred 14 adult patients to other institutions for bone marrow transplants and that six to eight pediatric patients are referred elsewhere for such transplants each year.

1-6-86

more

Schrier pointed out that the transplantation task force was designed by Dean David Korn of the medical school to be "super-departmental" because transplantation involves several departments.

"For example," he said, "renal transplantation involves certainly surgery, medicine and pathology. Bone marrow transplantation has pathology, medicine, pediatrics and radiation therapy—just to begin with and that's on the effective clinical level. On the other end there's the research input."

Research capability is one of Stanford's major strengths in recruiting members of the transplantation teams. "We have some of the world's best immunologists," Schrier said, "and immunologic manipulations are key to the success of the transplantations. We certainly have enormous strengths in that area—tissue typing and the ability to modulate the immune response."

Stanford also will have the new Center for Molecular and Genetic Medicine, which is scheduled for ground-breaking next June. "One of the things we're doing as part of our recruiting process is letting candidates know that the opportunity for interaction with the CMGM is a key to the success of the program," Schrier said.

The intent is for Stanford to become a major center for several types of transplantations, he said, and once the kidney and bone marrow procedures are in place there will be consideration of other organ transplants.

He said that in task force discussions about the next step "the thing that really intrigued us is that if some of the technical problems were solved, we could get into pancreas transplantations. There are a lot of diabetics who would benefit from a new insulin-secreting pancreas."

The technical problems are on the way to being solved through experiments with animals, he said, although "the trick in getting the human transplantation easily successful is still a little bit elusive."

Stanford's task force also considered liver transplantation, but Schrier said there are "horrendous" problems with such operations and there seems to be little sentiment for getting into that field at present.

Dean Korn told the executive committee that the personnel and office space needed to start the kidney and bone marrow programs will come out of existing medical school billets and space. "There is nothing yet identified as a major expense not covered in the table of organization," he said.

STANFORD RESEARCHERS OFFER STOP SMOKING PROGRAM

STANFORD—

A do-it-yourself program that helps individuals stay off cigarettes now is available to Bay Area residents as part of a Stanford University Medical School research program.

The eight-week Stanford Stop Smoking Program includes no group meetings and is offered at no cost to participants.

"Most smokers who have quit have done it on their own, and most people prefer not to attend group sessions," said Dr. Stephen Fortmann, principal investigator in the project and assistant professor of medicine at the Stanford University School of Medicine.

Although smokers often quit cigarettes for a short time, Dr. Fortmann explained, most eventually start smoking again. The Stanford Stop Smoking Program is an attempt to counter this fact.

Only two visits to a project center—at the beginning and end of the program—are involved. Researchers will collect follow-up information from participants throughout a two-year period.

The study's main facility is located on the Stanford University campus; satellite centers are located in San Jose and Oakland. Smokers who are 18 to 64 years old and who are determined to quit smoking are encouraged to contact the nearest center.

Stanford researchers joining Dr. Fortmann as co-investigators in the study are behavioral scientists Dr. Joel D. Killen and Dr. Michael J. Telch. Funded by the National Cancer Institute, the program is based in the Stanford Center for Research in Disease Prevention, of which Dr. Fortmann is an associate director.

For details, contact the nearest facility: Stanford Clinical Research Facility, (415)497-6254; Oakland Satellite Center, (415)633-1651; or San Jose Satellite Center, (408)977-4653.

YOUNG HEART PATIENTS FEATURED IN FILM PREMIERING AT STANFORD

STANFORD—

"A Different Heart," a documentary film on children with congenital heart disease, will have its premiere at 2 p.m., Saturday, Jan. 11, in Fairchild Auditorium at the Stanford University Medical Center.

The 20-minute film, produced by Itaka Schlubach-Hicks as her master's thesis for the Stanford department of communications, features three young patients at Stanford Hospital.

They are 4-year-old Juliana Ross of Gilroy, 11-year-old Jason Heppler of Cupertino and 15-year-old Steve Fields of Stockton.

All are now reasonably healthy and active, but at one time they all suffered from potentially fatal heart defects. The film shows how those defects affected the youngsters and their parents.

Lorraine Ross, mother of Juliana, expressed the emotion of most parents:

"Finding out that your child has any kind of health problem is probably one of the most monumental experiences in your life. It changes the course of your life forever."

A good part of the film explains how the parents adjusted to their children's illnesses and how the youngsters eventually accepted the fact that despite reasonable good health there were some kinds of physical exertion that were too strenuous for their participation.

The three children in "A Different Heart" are not isolated examples. Approximately one out of 100 infants is born with a heart defect, although sometimes the defect is so mild that a person can go through life without becoming aware of it.

Advances in medical care have greatly increased the chances of survival for infants with congenital heart defects. The film points out that Steve and Juliana probably would not have survived if they had been born a few years earlier than they were.

Schlubach-Hicks received a $7,500 grant from the Louis B. Mayer Foundation to help finance the film; the rest of the $14,000 cost came from her own funds and a few donations from interested individuals.

A preliminary version of the film, called "Jason," won honorary mention at the Palo Alto Film Festival in May 1985.

Information and assistance on the film was provided by the Stanford Hospital staff and by members of "Parents for Heart," a group sponsored by the Santa Clara County chapter of the American Heart Association.

The premiere of "A Different Heart" is being sponsored by the hospital and the Stanford department of communications. After the film, Schlubach-Hicks, members of the hospital staff and the families in the film will answer questions from the audience.

The showing is free, but space is limited and those wishing to make sure of seats are advised to call (415) 325-8878 for reservations.

STANFORD PUTS RESEARCH TO USE, IMPROVES HEALTH OF EMPLOYEES

STANFORD—

Steve Papier weighed 224 pounds, his blood pressure was a threatening 150/94 and his heart pounded away at 131 beats a minute after he finished a three-minute exercise test.

Three months later, he weighed 194, his blood pressure was 120/80 and his post-exercise heart rate was 94.

Papier is one of the major beneficiaries of a Stanford University health program that makes practical use of a decade of research at the university medical center into methods of improving health.

His physical improvement was the result of regular exercise and it involved a lot of effort on Papier's part—but it might not have happened without the intervention of the Stanford Health Improvement Program (HIP).

HIP enrolled Papier and about 50 co-workers from Stanford's department of Operations and Maintenance/Utilities in a special exercise program tailored for the skilled workers in the department. It helped a lot of the men in the department, but nobody more than Papier. And he has continued to show gains. Now, more than a year after the program ended, he still exercises regularly through HIP classes.

Aside from the individual benefits to people such as Papier, there were benefits to the department operation. Jerry Ostrander, who was director of Operations and Maintenance/Utilities at the time, wrote:

"I cannot estimate the dollar value of this program to us in reduced stress, more physically fit employees, hopefully less sickness, certainly less injury from pulled muscles/backstrain."

That program, of course, was just one of dozens of health and fitness offerings directed by HIP, which is a division of the Stanford Center for Research in Disease Prevention. HIP is sponsored by the university and hospital personnel departments and offers classes for all faculty and staff members and their families.

Classes cover most of the principal forms of exercise, as well as other areas beneficial to health. There are classes in aerobics, swimming, weight control, stress management, nutrition and smoking cessation. HIP officials are always ready to add to the list. A new class in walking is starting this month, for example.

Fran Carl is the HIP program manager and the person responsible for day-to-day operation. Dr. John Farquhar is the director and he was the principal force behind the start of HIP in 1982.

As director of the Center for Research in Disease Prevention, Farquhar has been actively involved in studying and implementing health promotion programs, particularly those aimed at reducing the risk of cardiovascular disease.

"We developed all those methods over the past decade," he said, "and many other places were trying them out. It seemed wrong to be helping the rest of the world and not doing anything in our own baliwick."

STANFORD MEDICAL SCHOOL RECEIVES $12.6 MILLION FOR NEW DEVELOPMENTAL BIOLOGY DEPARTMENT

STANFORD—

Stanford University School of Medicine has received a $12.6 million grant from the Lucille P. Markey Charitable Trust to support the establishment of a Department of Developmental Biology, the trust announced Wednesday, Jan. 8.

The new department will be a component of the new Center for Molecular and Genetic Medicine, whose construction will begin this summer, said Dr. David Korn, vice president and dean of the medical school.

"Our grant," said Louis J. Hector, chairman of the Miami-based trust, "recognizes the existing strength in biomedical research at Stanford, and the opportunity now to build on that strength and ensure further significant advances in the understanding of the complex process of development."

The funds provided to Stanford will be used to support additional faculty members, staff and initial research, as well as to provide laboratory equipment. The new department is one of four academic units that comprise the $50-million Center for Molecular and Genetic Medicine directed by Dr. Paul Berg, a 1980 Nobel prize winner in chemistry.

The center will allow scientists to bridge molecular biology and clinical practice—a field that, scientists say, promises dramatic changes for medicine in the future.

Developmental biology, one of four units to be included in the center, is a fundamental science likely to have an impact on genetic medicine. Its focus is understanding how the complex multicellular structures of the adult organism result from the fertilized egg.

"One benefit of an enhanced basic understanding of development is the more effective transfer of discoveries from basic research to the study of human disease," Berg said. The other units in the center will be biochemistry, molecular and cell physiology, and the Hughes laboratory in molecular and genetic medicine.

The grant will enable Stanford to begin recruitment of eight faculty members for the new department split evenly between promising junior scientists and more established investigators, with the majority being newly recruited, Berg said.

The goal is to create a principal center of research and teaching by creating a focal point of communication and collaboration among scientists throughout the university whose research impinges on problems of development, Berg added.

Other funding for the Center for Molecular and Genetic Medicine at Stanford has been provided by the Arnold and Mabel Beckman Foundation of Corona Del Mar, and the Howard Hughes Medical Institute. Fundraising efforts are continuing for the remaining $12 million needed for the project, said Stephen Peeps, associate director of medical center development.

In addition to the Stanford grant, the Markey Trust announced a $12.5 million grant to the California Institute of Technology, Pasadena, to assist the institution in expanding its developmental biology program; and an $8.7 million grant to the University of Chicago's neurosciences research program.

The trust was created by the late Lucille Parker (Wright) Markey, who directed that all funds be spent by 1997 exclusively for supporting basic medical research. The estate, now in probate, is expected to total more than $300 million. Mrs. Markey was the owner of the famed Calumet Farm, a thoroughbred breeding operation and racing stable based in Lexington, Ky.

NEW STANFORD DIVISION AN EXAMPLE OF DRAMATIC DEVELOPMENTS IN HAND SURGERY

STANFORD—

Few if any modern physicians place any credence in the ancient gypsy art of palm-reading, but many physicians actually are themselves expert at a type of palm-reading.

Three physicians at the Stanford University School of Medicine, for example, can give an accurate reading of many patients' medical problems simply by looking at their hands. They can see indications of congenital heart disease, neurological disease, hyperthyroidism and a host of other medical problems.

The physicians, all members of the new division of hand surgery at Stanford, are Dr. Vincent Hentz, Dr. Robert Chase and Dr. Vincent Pellegrini. They have all spent years studying the human hand and to them there is nothing unusual about finding disease symptoms in the hands. After all, physicians since the time of Hippocrates have known that some symptoms manifest themselves in the hands.

But Hippocrates couldn't have dreamed of the medical advances that are almost routine to the Stanford surgeons: replantation of severed fingers and hands, substitution of toes for useless or missing thumbs and fingers and implantation of artificial joints throughout the hands and arms.

Most of those surgical techniques have been perfected since World War II and the greatest advances have come in the past 15 years.

Even greater advances—notably the transplantation of hands and arms—are forecast for the near future and Stanford is positioned to be a leader in any such developments through its division of hand surgery, the first of its kind at any major medical school in the United States.

Each of the three members of the division brings a particular expertise to the program. Hentz, head of the division, is a specialist in microvascular surgery; Chase, internationally known as one of the "deans" of hand surgery, is interested in anatomy and hand imaging techniques and robotic substitutes for upper limbs for severely disabled patients; and Pellegrini, who came to Stanford in July from the University of Rochester, New York, is an orthopedic surgeon specializing in arthritis and disorders of the wrist.

All three physicians admit that the new division would more properly be called the division of hand and upper extremity surgery. Reconstructive surgery of hands can often involve surgery on arms or shoulders, and all of the surgeons work on the upper extremities as well as the hands.

Hentz sometimes is involved in even more exotic surgery because of his ability in microsurgery—which involves cutting and splicing vessels, nerves, muscles and tendons with minuscule tools maneuvered by peering through microscopes. (Chase says flatly that Hentz is "one of the world's experts in the field.")

One of Hentz' more unusual surgical challenges was reattaching the scalp of a man who had lost it when his long hair got tangled in a machine that simply ripped the scalp off. The surgery, using microsurgery to repair arteries and veins, was a complete success; the reattached scalp even survived a subsequent accident that left it split and bleeding.

more

1-8-86

That patient was brought to Stanford from Alaska on an emergency flight, and there are others who are rushed to the hospital by helicopter, landing just a couple of hundred yards from the emergency room. But Hentz has lots of stories about other patients arriving in more or less routine fashion, such as the contractor who flew from San Diego to San Francisco on a PSA jet, carrying his amputated thumb with him in a small ice chest.

Almost all of those stories have a happy ending, with patients leaving the hospital with replanted thumbs or fingers. Replantation has become a frequently performed operation and the public has come to take for granted surgery that only a few years ago prompted newspaper headlines.

The replantation operation isn't simple, but it usually is successful. And even when it isn't a success at first, there are several options available to modern surgeons.

Take, for example, the case of an 8-year-old boy who came to Stanford two years ago after losing all of his fingers, including the thumb, when a hand got caught in a machine.

"We must have spent 25 to 30 hours in the operating room over the weekend, trying to save his fingers," Hentz said. "But they were too badly damaged; he lost them all."

The subsequent steps involved psychology and patience. The boy's family wanted him fitted with a prosthetic hand, and doctors cooperated, even though, Hentz said, "Our feeling was that the experience that boy would have would be similar to that of other young people with a prosthesis where the other hand is normal. That is, the prosthesis winds up in a drawer; it's just too much trouble."

That's exactly what happened, and recently the family members came to Hentz and agreed with what the physicians had felt all along was the best solution: Taking toes off a foot and turning them into fingers on the hand, where they can be used to pinch and grab.

The result may be an unorthodox appearing hand, Hentz said, but "he'll go from being someone who does things with just one hand to using both ... to being a two-handed person."

That kind of operation may be more dramatic than one to replace an arthritic joint in the hand or upper extremity with a prosthetic implant, but the results of the latter surgery are certainly dramatic to a patient who has improved function and is often free of pain for the first time in years.

Most of the joint replacement that is done today is for the relief of pain from arthritis, Pellegrini said, and a lot more work has been done with hand implants than with the rest of the upper extremity. However, total shoulder replacement has compiled an excellent track record in the past ten years and with recent advances in implant design an equally bright future may be in store for elbow joint replacement.

The trend in hand implants, he said, is toward the use of natural tissue instead of silicone replacements, particularly in areas such as the wrist where there is a lot of stress. That's because the natural tissue doesn't wear out and silicone implants sometimes do, especially in areas that are under a great deal of stress or in younger people who are likely to have the implants a long time.

About 20 percent of the patients in the hand surgery division have arthritis or some other disease; roughly 30 percent have congenital problems or miscellaneous infections or tumors; and 50 percent have some kind of injury.

In the country as a whole, hand and upper extremity problems account for a staggering proportion of hospital visits. An estimated one-third of all emergency room visits are for injuries to hands or upper extremities and such injuries are responsible for about 16 million days lost from work each year. In addition, there are 25 million arthritis sufferers and three million people with some kind of hand or upper extremity impairment.

more

Those figures translate into a lot of work for the Stanford hand surgeons. In the 1983-84 fiscal year, before the special division at Stanford was established, there were about 4,000 patient visits to the hand surgery clinic. That's a sharp increase in the 10 years Hentz has been at Stanford. He recalls that when he joined the faculty in 1975, "we were seeing about 12 patients a week in one little clinic."

Chase has memories of Stanford that go back a bit further, and he has memories of hand surgery that go back almost to World War II, when it really emerged as a specialty.

In fact, Chase is directly responsible for much of the progress in reconstructive hand surgery at Stanford. When he became chairman of Stanford's surgery department in 1963, he set up a reconstructive and plastic surgery specialty section within the department. And he invited Dr. Harry Buncke to share in the use of Stanford's laboratories for research and teaching. Under Buncke's leadership, several of Stanford's young surgeons have themselves become renowned in microsurgery.

Chase also performed one of the notable operations in Stanford's history when he restored the almost-severed finger of Atlanta Braves' pitcher Cecil Upshaw. The surgery was so successful Upshaw was able to pitch the next year.

That was in 1970, before the development of the microsurgery techniques of today, and Chase had to transfer tissues from another finger, carried on their own tiny vessels and nerves, to repair the finger on Upshaw's pitching hand.

The next great step in hand surgery, Chase predicts, will be transplantation. As president of the American Society for Surgery of the Hand, he delivered an address in 1984 in which he compared progress in hand surgery over the past five centuries to a fire: "at first a small, long-smoldering spark, one that did not reach a kindling point until the beginning of the Twentieth Century; it has burst into full flame in the last two decades and presently seems ready to explode, as immunologic research brings transplantation closer to minimal risk and practical reality."

FEDERAL, STATE LAWS FOR ABUSED AND NEGLECTED CHILDREN 'WHOLLY INADEQUATE,' STANFORD STUDY CONCLUDES

STANFORD—

Abused and neglected children placed in foster homes may fare better than those left at home, but neither alternative is an adequate remedy for many of nearly one million children in the United States who fall into these categories, Stanford University researchers report.

Moreover, providing services to parents alone is not enough to change the cycle of abuse and neglect, conclude co-authors Michael Wald, professor of law, and Dr. Herbert Leiderman, professor of psychiatry.

Unless social and psychological services are geared toward the children as well as the parents they are simply "bandaids," Leiderman said.

Federal and state laws dealing with abused and neglected children are wholly inadequate, Wald and Leiderman said in their report to the California social services department. And programs to help children overcome developmental problems associated with abuse and neglect are lacking.

Legislatures must provide funding to develop such programs, they recommended. But these cannot be short-term or inexpensive and in many instances, both children and family may require several years of service.

Wald and Leiderman compared the physical, academic, social and emotional development of abused and neglected children placed in foster homes to those kept at home with their biological parents. The study was done in response to the "paucity of evidence regarding the impact of different intervention strategies"—home versus foster care—that Wald found while developing legal standards for protecting such children.

"If the only goal of public policy is to prevent severe physical harm to children, the current policy is justifiable," the authors said. "However, if legislators are concerned with children's academic, social and emotional development, as we believe they should be, legislators have to do more than adopt a preference for home or foster care. Under present policies, abused and neglected children remain at serious risk in both settings."

Present federal and state laws direct the courts and social service agencies to keep children in their homes as often as possible. Even though the victims' home situations may not be ideal, many experts argue, at least the children are spared the trauma of being separated from their own parents. And, it's often cheaper than paying for foster care.

1-9-86

more

"Sadly, we have found that current options leave the children in great distress," the researchers said.

"The social work system does not pay enough attention to the children themselves," Leiderman explained. "They're going on the assumption that if you help the parents, the children will be all right. Helping the parents may be necessary, but it is not sufficient in treating abused and neglected children."

Leiderman and Wald found that despite the social services provided, half of the children who remained at home were reabused or neglected. Many lived in fear of physical safety. Many bore the burdens of family conflict and were forced to cope with problems that their parents should have been handling.

The study included 65 children between the ages of 5 and 10 identified by the courts and child protection agencies as being abused and neglected. Of the 65 children, 36 remained at home and 29 were placed in foster homes. The children were evaluated for a two-year period.

The study originally included white, chicano and black children. However, the final report did not include the minority children because the researchers were not able to obtain enough data about them.

While the researchers pointed out that limitations of the study include the small number of participants and the lack of minority involvement, it nonetheless establishes that what may be correct intervention for white children and their families may not be good for minority children and their families. "Their experience with abuse and neglect is different," Wald and Leiderman found.

The researchers interviewed the children, parents, teachers and social workers to measure the children's physical health, cognitive development and social behavior at home and school. They also tried to assess the children's perspectives about their own lives.

While "you cannot try to generalize or draw any conclusions from a study of 32 white children," Wald and Leiderman concluded, "we've raised some interesting issues for other researchers to consider."

What they found is that for home children, "the academic performance remained below what would be expected based on their IQ scores. Nearly half of the home children continued to miss substantial amounts of school. Relations with their parents remained poor; nearly half of the children continued to have significant emotional problems.

While neither group of children improved considerably, the researchers found, those placed in foster homes seemed to be better off in terms of improved physical health, school attendance, academic performance and social behavior at school.

"The stress caused by the conflict in the home environment may have had a more negative impact on the home children than the stress that separation and adjustment to new 'parents' had on the foster children," Wald and Leiderman said.

NEW GUIDELINES EMPHASIZE SPEEDY RECOVERY FOR LOW-RISK HEART PATIENTS

STANFORD—

Early, systematic evaluation can hasten the recovery of patients after heart attack and coronary artery surgery, according to an article in the January 16 issue of *The New England Journal of Medicine*.

Nearly half of all heart attack and three-quarters of bypass surgery patients have a very low risk of a second heart attack or death during their first year of recovery, said the article, co-authored by researchers from 12 university medical centers.

These low-risk patients don't benefit substantially from further diagnostic or treatment procedures, the article adds.

The article contains the first published set of guidelines for physicians on how to identify and treat low-risk heart patients, said Dr. Robert DeBusk, the lead author.

"What low-risk patients need from physicians are explicit recommendations about safe levels of physical activity and reassurance that they can soon resume normal lives," said DeBusk, a cardiologist and professor of medicine at Stanford University School of Medicine.

"These guidelines present a systematic approach to diagnosis and treatment which will enable physicians to provide this information to patients," he said.

"The guidelines are based on experience with thousands of patients who have undergone systematic follow-up during the past decade," he added.

The report stresses the role of exercise stress testing, performed alone and in combination with other techniques such as radioisotope imaging, in evaluating the risk of subsequent heart attack or death in recovering patients.

Exercise testing involves walking on a treadmill or pedaling a stationary cycle while heart rate, blood pressure and electrocardiogram are monitored. Radioisotope imaging is a method of using radioactive substances to obtain pictures of the blood flow to the heart muscle and the strength of contraction of the heart's pumping chambers.

Physicians can use exercise testing and radioisotope imaging to measure two important aspects of heart function—the extent of impairment of the heart's pumping ability and the extent to which blood flow to the heart muscle is impaired—under conditions similar to those encountered by patients in their normal activities, DeBusk explained in an interview.

These two measures of heart function help the physician predict both prognosis, or the patient's risk of subsequent cardiac problems, and the patient's functional capacity, or ability to perform physical work, DeBusk said.

A stepwise diagnostic approach, outlined in the report, enables physicians to distinguish high-risk from low-risk patients, he added.

"Within the first week of hospitalization, it is possible to identify 20 percent of heart attack patients who have clinically evident impairment of heart function that places them at high risk," DeBusk said, "and by the end of the second or third week, it is possible with exercise testing to identify an additional 30 percent who have less obvious impairment of heart function that nonetheless places them at moderate or high risk."

More than ten percent of these moderate- and high-risk patients die within their first year of recovery, the article said. Moderate- and high-risk patients are appropriate candidates for coronary angiography, coronary artery bypass surgery, or balloon dilatation, a procedure that opens narrowed coronary arteries, DeBusk said.

"The remaining 50 percent of patients have a very low risk of heart attack or death within the first year—less than two percent," DeBusk explained.

"These are the patients who benefit least from further evaluation or treatment and who are most capable of resuming their customary activities, including occupational work, at an early point," he said.

A similar stepwise approach can be used to identify low-risk bypass surgery patients, DeBusk and his colleagues suggested.

"Because medical research in recent years has emphasized high-risk patients, many physicians don't realize how large the low-risk group really is," DeBusk noted.

"Since approximately 800,000 patients in this country survive an acute myocardial infarction (heart attack) and another 180,000 undergo coronary-artery bypass surgery each year, the distinction between low-risk and high-risk patients has important economic and public policy implications," the authors wrote.

The other authors of the report are Gunnar Blomqvist, MD (University of Texas Health Science Center); Nicholas Kouchokos, MD (Washington University School of Medicine); Russell Luepker, MD (University of Minnesota School of Medicine); Henry Miller, MD (Bowman Gray School of Medicine); Arthur Moss, MD (University of Rochester School of Medicine); and Michael Pollock, PhD (University of Florida College of Medicine).

Also, Joseph Reeves, MD (University of Texas School of Medicine); Ronald Selvester, MD (Rancho Los Amigos Medical Center); William Stason, MD (Harvard School of Public Health); Galen Wagner, MD (Duke University School of Medicine); and Vallee Willman, MD (St. Louis University School of Medicine).

The report was developed with grant support from the American Heart Association.

PSORIASIS SEMINAR SCHEDULED

STANFORD—

A free one-day educational session for psoriasis patients and their families has been scheduled Saturday, Jan. 25.

Dr. Lexie Nall of the Stanford Medical School's Department of Dermatology said the session is to be be held from 10 a.m. to 4 p.m. at the Psoriasis Research Institute, 600 Town and Country Village, Palo Alto.

The cause and course of psoriasis, treatment, preventive measures, myths and research will be discussed, she said. Slides, lectures, and discussions with patients and health care professionals will be augmented by handout materials participants can take home.

Psoriasis, a worldwide problem affecting millions of people, is caused by a little understood overproduction of certain cells. It can be triggered in genetically predisposed persons by a variety of factors, including injury to the skin, sun, prolonged low humidity or medications. It is not contagious.

The course of the disease is unpredictable, and recurring flareups can be particularly stressful for patients, Nall explained.

The course is sponsored by the Department of Dermatology and the Psoriasis Research Institute. For further information, contact Nall at (415) 497-7967.

VOLUNTEERS WITH DIABETES RECRUITED FOR TWO STUDIES

STANFORD—

Stanford researchers are seeking older patients with diabetes as volunteers for two projects.

One study, conducted by the Stanford Diabetes Clinic, is attempting to learn if a new oral medication, linogliride, is effective at controlling diabetes. Volunteers must be Type II adult onset diabetics between 40 and 70 years old in generally good health.

Participants may or may not be taking insulin to help their condition but must be able to give up that medication during the study, said Dr. Elizabeth Fraze, a fellow in endocriniology.

The linogliride study is headed by Dr. Fredrick Kraemer, director of the diabetes clinic. Persons interested in further information should call Fraze at (415) 497-5947 or 497-6054.

The second study needs Type II (adult onset, non-insulin dependent) diabetics to evaluate the relationship between diabetes and mental functioning.

Funded by the National Institute of Aging through the Teaching Nursing Home Award to Stanford University, the project will require an overnight stay in the Aging Study Unit at the Palo Alto Veterans Administration Hospital.

Project coordinator Gwen Yeo said participants will undergo a series of physical and psychological tests. Results will be provided to volunteers at no charge to them, she said.

For further information on the aging project, contact Yeo at (415) 497-7063 or 493-5000, ext. 2006, or project director Larry W. Thompson at (415) 858-3989.

Fraze said about 80 percent of the estimated 5.5 million diabetics in the United States suffer from Type II adult onset diabetes mellitus, a metabolic disorder in which the body fails to process carbohydrates properly. Strict attention to diet, as well as medication including insulin, are common treatments.

NOTE TO EDITORS: After the groundbreaking ceremonies described in the accompanying release, from 10:30 to 11:30 a.m. Jan. 22, there will be an opportunity to interview a couple staying in one of the Oak Creek apartments supported by the Assistance League. They are Beatrice and Larry Strobel and both suffer from multiple sclerosis. They are awaiting the birth of Beatrice Strobel's first child. The Strobels have agreed to be interviewed in their apartment, which will provide an opportunity for photographs of a living situation similar to that expected in the Hewlett apartments. Please inform the Medical Center Office of Communications if you are interested in interviewing the Strobels.

FOR IMMEDIATE RELEASE

CONSTRUCTION STARTING ON UNIQUE 'HOMETEL' AT STANFORD MEDICAL CENTER

STANFORD—

Groundbreaking ceremonies will be held Jan. 22 for the Flora Lamson Hewlett Apartments, which will provide short-term, low-cost lodging near the Stanford University Medical Center for out-of-town patients and their families.

The 42-unit building, which has been informally labeled a "Hometel," is the result of a unique cooperation between the university, the William and Flora Hewlett Foundation of Menlo Park and the Assistance League of Santa Clara County.

Stanford provided the land for the apartments under a $1-a-year lease, and the construction is being financed by a $3,750,000 grant to the Assistance League from the Hewlett Foundation. The building is named for Flora Lamson Hewlett, the late wife of William R. Hewlett and one of the foundation's founders.

The building, at 1100 Welch Road, will be owned and operated by the Assistance League of Santa Clara County, a chapter of the National Assistance League, a volunteer service organization. The bulk of the operating funds will come from the Costume Bank in Los Altos, the principal fund raiser for all of the chapter's philanthropic activities.

The project is apparently unique in American health care circles. A handful of U.S. hospitals provide nearby housing for patients and families, but as far as is known this is the first time such housing has been provided through the cooperation of institutional and private interests.

Simultaneously with the Hewlett building, Stanford will build an adjacent 108-unit apartment project intended primarily for use by medical center employees. Construction of both projects is expected to be completed by June of 1987.

Hospital outpatients and families who stay in the Hewlett Apartments will pay $10 a day, a fraction of the cost at hotels and motels in the area. Occupancy will be limited to those whose homes are at least 50 miles from the medical center and stays will be restricted to nine weeks.

Potential occupants of the apartments will be screened by the hospital's division of social services, and the members of the division will make the decision on who gets to use the apartments.

Such a system has been operated successfully at five apartment units the Assistance League has leased for patient housing at Oak Creek Apartments, across Willow Road from the Hewlett Apartments site at the intersection of Welch Road and Pasteur Drive. The league began the project in 1979 by leasing two one-bedroom apartments and has gradually increased the number of apartments available to families and patients at the $10-a-day rate. More than 300 families have been helped since the rentals started and all five units have had 100 percent occupancy with long waiting lists.

more

2-2-2

The Assistance League's involvement with patient housing goes back even further than 1979. It started with personal experiences, according to Kay Clair, chairwoman of the league's HOME (Housing for Medical Emergencies) project.

"Many of our members had personal experiences with family and friends with cancer," she said. "Being at the hospital day after day, seeing relatives in the waiting rooms, we became aware of the desperate need for patient and family housing near the hospital."

That awareness prompted a 1976 study by Assistance League volunteers of the housing needs of patients and their families. The study, in turn, led to the leasing of the Oak Creek apartments and the establishment of a formal housing program.

League members soon realized, however, that the Oak Creek facilities were inadequate to meet the needs of patients and families seeking housing. In 1980, Jeanne Kennedy, director of patient and community relations at Stanford Hospital, began working with Clair on a plan for a separate building to house patients and families.

Three years later, that plan resulted in the grant from the Hewlett Foundation to the Assistance League and the HOME project became a major enterprise.

The Hewlett Apartments will average 640 square feet. Each will have a bedroom, living room, kitchen and bath and be designed to accommodate two people. There will be a communal lounge and laundry facilities and residents of the apartments will be able to use the swimming pool at the adjacent Stanford complex. There also will be a full-time resident manager, whose salary will be paid by the Assistance League.

"One of the great things about the project is that it eases the financial burden on patients and their families who come from a distance," said Kennedy. "Besides the hospital costs, they have the extra expenses of housing—which in this area is very expensive—plus eating out, transportation and similar items. This alleviates those expenses. They have inexpensive accommodations, they can cook their own meals and they're just a short distance from the hospital."

Karen Walles, who is coordinating the groundbreaking ceremonies for the Assistance League, noted that Stanford has some patients who come from foreign countries. Having housing available near the hospital is particularly important for them, she said.

To Kay Clair, who has been involved with every phase of the project since the first survey 10 years ago and who was presented Stanford Hospital's distinguished service award for that work, the building represents "a dream about to become a reality."

"I can't believe it's finally happening," she said. "It's kind of a fitting way to celebrate our (the league's) 25th anniversary."

Clair knows how much the Hewlett Apartments will mean to some hospital patients. She showed some of the letters the Assistance League has received from grateful occupants of the league's apartments at Oak Creek.

"My husband has been terribly ill with cancer and I am unable to work due to a heart problem," one woman wrote. "Consequently, it would be almost impossible to stay here for his radiation therapy without this help. Thank you and God bless you."

Another woman wrote of her experience on arriving at Stanford: "We had tried all types of possibilities and were really at the end of our rope and our pocketbooks. I was overwhelmed by the apartment and motel prices in that area."

After a five-week stay in one of the apartments, the same woman and her mother expressed their gratitude in concrete ways: "Before we left the apartment, my mother reupholstered three of the dining room chairs that were worn through to the wood, and I added a place setting for four to the silverware in the kitchen. Thanks again for everything."

FOR IMMEDIATE RELEASE

TO EAT OR NOT TO EAT—ONLY YOUR COMPUTER KNOWS

STANFORD—

Behavioral scientists at Stanford University School of Medicine are using microcomputers to treat obesity.

In a recent study, published in the *Journal of Consulting and Clinical Psychology*, six obese patients were equipped with an interactive microcomputer system small enough to be carried in their daily routines.

Treatment results in the six patients were compared with those in six matched controls who received similar treatment but monitored its effects using paper-and-pencil methods.

"Patients who received computer-assisted treatment lost about 2.5 times as much weight compared to patients who relied on self-monitoring," reported Drs. Kent F. Burnett, C. Barr Taylor and W. Stewart Agras of the Laboratory for the Study of Behavioral Medicine.

The study is significant, Agras explained, because behavioral treatment for obesity relies heavily on self-monitoring to provide continuous feedback. When such feedback is delayed until the next meeting with the therapist so are the essential therapeutic instructions and reinforcement. That is by no means ideal.

"Technical advances in portability of microcomputers now provide new pathways for fulfilling the potential of behavior treatments based on self-monitoring," the researchers reported.

Volunteers in the study were women between 30 and 50 years of age, and about 35 percent overweight. The volunteers were equipped with a portable, battery-operated computer developed for the project. The computer, weighing two pounds, was carried in a pouch on a shoulder strap and was capable of 45 days of continuous operation.

A keypad permitted users to enter data into the computer and messages were displayed in a liquid crystal screen. The system included a clock that tracked collected data chronologically, a programmable beeper signal and capacity to process and transfer physiological data to another computer for storage and analysis.

Volunteers in the computer-assisted therapy program made regular reports on their eating behavior ranging from snacks to regular meals and exercise. Although the volunteers were expected to make reports following each of these activities, the beeper signal also reminded them to make self-reports every four hours.

Volunteers entered codes for reports on food consumption and physical activity, including duration of exertion. The computer not only stored data, but following the self-reports, it displayed for the patient's benefit the total calories reported, and remaining caloric intake limit for the day.

The computer also provided praise and instructions. If the data indicated that caloric intake had exceeded daily limits, the computer instructed the volunteer to stop eating and recommended alternative behaviors. If the data indicated caloric intake within prescribed limits, a message was displayed praising the volunteer with the words, "Fantastic! (subject's name), You have Self-Control!"

1-21-86

more

In the control group, similar information codes were used for self-monitoring, but the data were entered by the volunteers into a hand-written form.

While the computer-assisted volunteers could look up and analyze their code values in their portable computers, the controls had to look up and tally these values themselves in their hand-written forms. And they had no beeper signal to remind them to make reports and receive praise and instructions.

Throughout the study, volunteers in both treatments met with therapists once a week for 15 minutes to discuss progress and set goals. They also completed forms at home each week soliciting comments about the program.

While the results, because of the small number of patients, must be interpreted cautiously, stressed Dr. Agras and his associates, computer-assisted therapy opens new avenues for research in behavioral medicine.

One is discovering which learning principles incorporated into the computer programs are most influential in affecting therapeutic behavior change, they wrote.

"Because software-based therapy programs permit rapid modification of treatment components," they said, "it's possible to dissect and analyze the effects associated with diverse combinations of treatment components."

Beyond the scope of their study, the researchers noted computers in therapy raise many issues. How can they be developed for easy and friendly use? for example. How does the novelty or apparent mystery of the computer affect treatment outcome?

These questions must be answered, they added, "before we will be able to fully understand and exploit the potential clinical utility of this new technology."

BREAST CANCER THERAPIES IMPROVE BUT SURVIVAL RATES DON'T, STANFORD STUDY FINDS

STANFORD—

The good news for women diagnosed with breast cancer is that less destructive therapies are replacing mastectomies--removal of the breast and surrounding muscles--without lowering the cure rates, a Stanford University Medical Center scientist has found.

The bad news is that even with the improved therapies, the survival rate, adjusted for age since women live longer than they used to, has not significantly increased over the last 50 years, said Dr. Stanley Chism, assistant professor of radiation therapy.

His findings contradict other reports that show improving survival rates of "selected" populations.

What those reports are actually showing, Chism contends, is a change in the numbers of women being treated rather than a change in the treatment outcomes.

Women used to not go to a physician when they discovered a lump in their breast because they feared the treatment, he explained. By the time they came in for treatment, the cancer had often spread throughout their body.

Now however, improved diagnostic procedures such as mammography, health education programs and availability of health insurance are allowing physicians to identify patients with earlier stages of the disease, or "more favorable disease," Chism said.

"Women aren't dying of the local breast cancer itself, they're dying because it spreads through their body," he said. "It's clear that we need to put the emphasis on treatment for systemic cancers in order to be effective."

Chism recently presented his findings, the result of a study involving 530 women in a community, at the annual meeting of the American Society of Therapeutic Radiology and Oncology.

Meeting attendants were suprised to learn that the newest type of breast cancer therapy, biopsy and radiation treatment, is the most commonly used in some communities, Chism said. As of 1984, about 60 percent of patients in one Bay Area community opted for biopsy and radiation treatment, while less than 40 percent opted for radical mastectomy, he reported.

While the five-, 10- and 15-year survival rates were slightly higher for women treated in recent years, the number of women with more favorable disease treated doubled. This may explain the improved survival rates, Chism said.

Only about two percent of the women truly benefitted from one of the most advanced treatments, chemotherapy.

"You can look at it positively or negatively," Chism said. "Ladies now don't have to have a mastectomy to have the same likelihood of cure. Preserving the breast is a step forward. Yet, we have not significantly budged survival rates."

NEW ALUMNI DEAN APPOINTED AT STANFORD MEDICAL SCHOOL

STANFORD—

Dr. Patricia Engasser has been appointed Associate Dean for Alumni Affairs at Stanford University School of Medicine, announced Dean David Korn.

Engasser, a dermatologist at Kaiser-Permanente Medical Center, Redwood City, and a member of the voluntary clinical faculty at Stanford and University of California, San Francisco, will take on her new responsibilities Feb. 1.

Engasser was unanimously chosen for the associate deanship by the Committee on Alumni Affairs, appointed by Korn more than a year ago to examine the relationships between the medical school and its alumni and recommend ways to strengthen those ties.

In its report to Korn last June, the committee, made up of 12 full-time faculty and community physicians who are all alumni, recommended the creation of the part-time position.

"I would like to open up communication between the dean and the alumni," Engasser said. Specifically, she plans to establish regional alumni groups, update the alumni directory and cultivate an alumni network all over the country.

"I'd like to create more of an extended Stanford family," she said.

Engasser received her M.D. in 1962 and her undergraduate degree in 1959 from Stanford. She has served on the Stanford Medical Fund Council since 1977, and has chaired the Medical Fund since 1982. She has also served on the Stanford Medical Alumni Association Board of Directors since 1981.

"She is a thoroughly delightful person to work with and to know, and the high regard in which she is held by colleagues and students will doubtless be shared by all who will meet her in her new administrative role," said Korn in a letter to alumni announcing Engasser's appointment.

Engasser will be located in the medical center's Office of Public Events, 750 Welch Rd., 314, for the equivalent of one day each week.

"I hope to hear from lots of alumni to see what types of activities they'd like and to hear their concerns," she said.

More than 3,400 graduates of the medical school are members of the alumni association, and more than 1,750 physicians who completed training at Stanford are associate members.

NEW ANALYZER WILL HELP BONE PROBLEMS IN SPACE AND ON EARTH, STANFORD SCIENTISTS HOPE

STANFORD—

A Stanford engineer together with a NASA investigator have designed a bone analyzer that they hope will allow doctors to detect disease, as well as help scientists solve the bone wasting that can occur during space travel.

Just as physician "Bones" McCoy on the popular TV series "Star Trek" used a hand-held scanner to diagnose illness, the prototype analyzer, though mounted on a drill press stand, promises to give non-invasive measures of bone health.

Lack of the constant tug of gravity in space means that astronauts no longer need their long bones to support their weight. Similarly, prolonged bed rest or disuse of a limb due to chronic pain leaves bones with nothing to do.

According to Dr. Charles Steele of Stanford, co-inventor of the instrument,"If you don't use bones, you lose them."

Although by adolescence our bones have stopped lengthening, he explained in an interview, they never stop growing. Cells within bone tissue are constantly breaking down and reassembling the mineral matrix of the skeleton.

Daily activity prompts hormones to keep the rate of rebuilding equal to the rate of dismantling, Steele said. For instance, each step while walking puts a load on the leg bone of five times the body's weight. But if one is up in space, or kept in bed, he continued, "there is no load, and no regrowth."

Loss also exceeds repair in a condition called osteoporosis, which causes brittle bones and "dowager's hump" in "a substantial proportion" of women past menopause, Steele said.

Prolonged dialysis of patients with kidney damage, as well as therapy with anti-rejection drugs for transplants, also can affect metabolism of bones adversely, he said.

The bone analyzer would detect these harmful changes earlier than can other methods such as X-rays or photon absorption, Steele explained, because it directly tests the strength of bones.

"We get a direct measure of the functional property of stiffness," he said.

"We hope we can get enough precision to measure five percent changes in bone, to detect early stages (of bone loss) and judge the success of diet changes, exercise, or drugs," he added.

Dr. Donald Young, a NASA physiologist at the Ames Research Center in Mountain View, California, collaborates with Steele on the project, and initiated work with the analyzer approach.

Analysis begins by positioning a person's limb in place. A fingertip-sized probe then presses and vibrates against the long bone of a person's forearm or lower leg. The bone vibrates in response, but with a frequency that depends on its strength, or "how hard it is to bend it," Steele said.

01-22-86

-more-

An attached force transducer and accelerometer send data to a microprocessor system that analyzes the bone's resistance to being shaken by the probe.

Measurement of each limb takes less than a minute.

An objective number that indicates strength would be superior to methods medicine now uses to judge whether a fractured limb has healed, Steele pointed out.

Doctors take X-rays to view how healing progresses in a broken leg. But when they decide to remove a cast, all they can do is have the patient stand on tip-toe (which places a quick load on the bone) and tell if it hurts, Steele said.

A quantitative measure would be better, agreed Stanford professor of orthopedics Dr. Donald Nagel, who is helping Steele develop tests for fracture patients.

The bone analyzer has already quantified the degree of weakness that can follow disuse. One woman Steele measured had a shoulder injury that for four years kept her from lifting her arm. "She had a 68 percent drop in that bone's stiffness," he said.

Steele is also collaborating with associate professor Dr. David Schurman at the orthopedic clinic at Stanford University Medical Center. They will follow the recovery of bone strength in patients who receive joint implants and begin to use limbs that pain had kept idle.

Steele, a professor of mechanical engineering, said he is still trying to improve the mathematical formula that extracts information from the response of the bone. "We have a primitive algorithm right now," he admitted.

Because overlying skin, sinew, and fat mask the vibrations of bone in response to the probe, the computer must correct the readings, Steele explained. While the majority of body builds can already be handled accurately, he said, "we want an algorithm that will accomodate everyone."

NASA's Young hopes to develop exercises that would entertain astronauts as well as keep their bones from losing strength. Previous exercise routines involved treadmills that were both boring and ineffective in curbing bone loss, Steele said.

By carrying a version of the bone analyzer aboard space vehicles, astronauts could constantly measure their bones and adjust their activities to correct any detected weakening, Young and Steele suggest.

STANFORD UNIVERSITY HOSPITAL PLANNING STAFF REDUCTIONS IN RESPONSE TO COMPETITION, FEWER PATIENTS

STANFORD—

Stanford University Hospital, adjusting to sharp declines in patient stays and reimbursement limitations, is facing its first major reduction in personnel since the creation of Medicare and Medicaid 20 years ago led to a period of expansion for all hospitals.

"The decision to cut staff is painful, but essential for the institution's continued livelihood," said Hospital President Sheldon S. King.

The layoffs will not diminish the quality of care for which the hospital is known, he said. Reductions will enable the hospital to become more affordable and cost-competitive than it has been in the past in comparison to institutions of its class.

In the past four years in keeping with national trends the hospital's average length of stay dropped from 6.8 to 6.3 days, and patient days went from 156,654 (exluding newborns) to 140,552, King explained. The hospital is also staffed higher than similar teaching hospitals on the West Coast.

In a letter mailed to hospital staff Tuesday, Jan. 28, officials said they have not yet decided how many employees will be affected by layoffs. They called on all employees to understand the reasons behind the "painful decision," and stressed they are looking at ways to ease the transition for those who will be affected.

"Right now we are defining the details of the program," wrote Hospital Deputy Director William Arnold. "But we can tell you that we will make these reductions in a responsible way."

Reductions will be selective, not across the board, and administrators will be affected along with other staff. "Whenever possible, we hope to cut activities, not people," Arnold said.

The letter said an analysis to determine how and where cuts will be made is under way, with details to be announced when firm information is available.

"We expect to complete the process by the middle of April," Arnold said.

The 663-bed hospital has 4,239 employees, including those who work part-time.

"The cuts will enable the hospital to scale down its activities to a realistic volume of patients and trim $25 million from its $210 million operating budget in the coming year," King said.

"Members of the medical staff—both community and faculty physicians—will be working with administration on issues related to quality of care," King said.

Middle managers will participate in layoff decisions. "They understand best how their departments are run and can recommend choices that do not compromise the quality of care," he said.

"The cuts," King noted, "represent an acceleration of the cost management and expense reduction programs started by the hospital three years ago."

The hospital, Arnold said, will still reserve some funds for new program development. The hospital last year launched new programs, including Life Flight, trauma center, home care, and same day surgery. It also entered into contracts with several discounted health plans and similar cost-cutting programs.

The hospital began "downsizing" its operations three years ago to adjust to a lower level of patient days, King said. Its cost management effort succeeded in reducing expenses by $17 million. But it wasn't enough, and hopes that there would be an upturn in patient admissions or stays were not fulfilled.

The major causes of the decline in census, King said, are federal reimbursement policies and the number of unnecessary beds in the San Francisco Bay Area combined with a number of economic, medical and surgical innovations enabling many procedures to be done in outpatient clinics or hospitals to discharge patients more quickly.

"We know now the situation is permanent," King said. "This will be the prevailing approach to the way medical care is delivered over the next 25 years."

The reductions are not expected to affect the $114 million hospital modernization scheduled for completion in 1987. Stanford officials believe the project is an essential investment for correcting problems afflicting the present facility and creating an attractive and more efficient hospital for patients and their families.

As all hospitals in recent years, Stanford has entered into contracts with various health plans at considerable discounts in order to maintain its patient base, King said in citing other reasons for the layoffs. This means less income to the hospital and greater pressures on administration to operate the institution more cost effectively.

"Third-party payers, our medical staff, and the hospital board," King said, "have expressed concern about our costs."

The hospital's prices are similar to those of the University of California in San Francisco with which Stanford is often compared. But it is regarded as the most expensive hospital in Santa Clara County with an average daily charge of $1,498 per patient compared to $1,251 at Santa Clara Valley Medical Center and $1,000 less at community and tax-supported district hospitals.

"Because we are a teaching hospital, there will always be a cost differential," King explained, "but it has to be seen by both patients and insurers as reasonable and worth the difference."

The hospital can't continue to raise prices, King said. Most patients nowadays come under a fixed per diem or prospective reimbursement scheme covering their hospital care.

The future is equally uncertain, added King, who as past president of the Council of Teaching Hospitals has given testimony frequently before Congressional committees trying to trim Medicare's costs.

"The effect of pending legislation, for instance, is still speculative but it is unlikely to be favorable," King said.

The hospital executive reiterated a theme echoed by members of his staff. "The months ahead will not be easy," he said. "But we now have a chance to preserve and rebuild. Is it difficult? You bet. There's no management in the country that wouldn't prefer to be expanding. That's the easiest form of management."

In their efforts to find the most responsible process for staff reductions, King and his staff weighed the pros and cons of various options. These ranged from putting everyone on a shorter work week to phasing the staff reductions over a period of time.

"Despite the social value of some of these approaches," King said, "we agreed we merely postponed the inevitable.

"As a philosophy for the institution, it's our responsibility to make sure that those individuals who still have a place at Stanford hospital after the reductions take place are here as full participants and not penalized by uncertainty.

"When you postpone decisions of this sort for too long, it means also that you are making cuts in an unplanned way and often sacrificing services that are important."

EXPLORING THE GOMER PHENOMENON

STANFORD—

The term "gomer" and other informal language young physicians use to classify patients are more a reflection of their disillusionment stemming from medicine's limitations and dilemmas within the health care system rather than of their feelings about the patients, say the authors of a new study.

Gomer, the most popularized of the terms, refers to patients whose illnesses are never resolved: they do not die nor do they ever get well.

The term "captures universal human fears of illness, intellectual decline, loss of autonomy and aging as well as doctors' frustrations that modern medicine, which promises to do so much, too often fails to deliver on its promise," concluded Stanford University Medical Center senior neurology resident Dr. Deborah Leiderman and Dr. Jean-Anne Grisso of University of Pennsylvania's department of medicine.

The authors reported their findings, based on a study they conducted at University of Pennsylvania School of Medicine, in the September, 1985, issue of the *Journal of Health and Social Behavior*.

The authors noted that the terms are used primarily by housestaff—physicians-in-training—who are typically more idealistic and under more stress than older physicians who have more experience and perhaps are more realistic about what medicine is, and is not able to do.

"The inconsistencies in the system--the gap between the myth of omnipotence of technologic medicine and the realities of gomer patients on the wards--become starkly visible to young physicians in the early stages of professional socialization," they said.

Gomers, they explained, are patients who have more difficult diagnostic, therapeutic and behavioral problems. They often suffer more mental decline, stay hospitalized longer and are less often able to return to their own homes and usual adult roles.

1-23-86

-more-

2-2-2

The authors analyzed hospital records of gomer patients and interviewed housestaff about their attitudes and perceptions regarding gomers' treatment. The study compared 18 patients, labeled gomers by housestaff, with 18 general medical patients. They compared the patients' background characteristics, events occurring during hospitalization and outcomes.

The two groups were similar except that at the time of admission to the hospital the gomers were less active and had less ability to function in adult social roles. Also, nearly half of the gomers were in some way mentally impaired, compared with less than one-quarter of the general patients.

While the reasons for admission were similar for the two groups, the patterns of hospital stay drastically differed, the authors found.

Twice as many gomers suffered serious medical complications during hospitalization, the authors documented, and more than two-thirds suffered mental deterioration. Few gomers fully recovered, and three-quarters had some mental impairment at discharge. The general patients were able to resume their adult roles once they were discharged.

Because of their impairment, nearly one-half of the gomers--compared with only two general patients--were sent to nursing homes following discharge from the hospital. Nursing home beds are hard to obtain, however, resulting in the gomers' hospital stay being extended beyond medical necessity.

The longer the gomers stayed in the hospital, the more frustrated physicians caring for them became, the authors said.

"Gomers may be seen as an index of medicine's insoluble problems . . .that lead to neither death nor cure," they continued. Gomers "confront residents with two profound threats to their ideals of themselves as physicians." Their lingering presence challenges physicians' ideals about the powers of medicine, and forces the young physicians to confront uncertainty "arising from the limits and gaps in the present state of medical knowledge and perhaps from doubts about their own competence."

NEW HEAD OF STANFORD HEART-LUNG PROGRAM NAMED

STANFORD—

Dr. John C. Baldwin, a cardiovascular surgeon and board certified internist, will head Stanford University's heart-lung transplant program.

Dr. Norman Shumway, transplant pioneer and chairman of Stanford's Department of Cardiovascular Surgery, announced Wednesday (Jan. 29) that Baldwin will succeed Dr. Stuart Jamieson effective April 1.

Jamieson has been named professor of surgery and chairman of cardiovascular surgery at the University of Minnesota. Jamieson will also direct a newly-formed Minnesota Heart and Lung Institute, a multidisciplinary surgical and medical center for research and treatment of cardiovascular disease, the Minneapolis-based medical center announced Wednesday.

"It's exciting to see such bright young surgeons come through our program," said Shumway. "The patient care and scientific investigation involved with heart-lung transplantation will continue to develop under John Baldwin. He is a Rhodes Scholar with outstanding intellectual and research qualifications and superlative surgical and medical skills."

Shumway said that Baldwin's internal medicine training should bring extremely useful insight into both the management of patients following surgery and the ability to explore research questions on a very broad basis.

The heart-lung transplant program evolved from Stanford's research and clinical experience in heart transplantation, which started with Shumway's early animal experiments in the 1950s. These were followed with one of the world's first human heart transplant operations in January 1968. Then in March 1981, a Shumway protege, Dr. Bruce A. Reitz, led the team which performed the world's first successful combined heart-lung operation at Stanford on a 45-year-old Arizona woman, Mary Gohlke, who currently is reported active and doing well.

Jamieson took over leadership of the dual-transplant service in July 1982 after Reitz left to head the cardiac surgery program at Johns Hopkins University.

Stanford remains one of the most active cardiac transplant centers in the world with nearly 370 heart transplants and 30 heart-lung transplant operations on 29 patients to date (one patient received two sets of organs).

Jamieson, who came to Stanford eight years ago as a postdoctoral fellow in cardiovascular surgery, said in an interview that he has seen during his time here a progression in cardiac transplantation "from a somewhat exotic clinical research venture to an important therapeutic procedure now performed routinely in major centers throughout the world."

Now, both he and Baldwin are interested in solving at their respective centers the problem of scarce donors, one of the major hurdles to expansion of the therapeutic technique.

Baldwin said he is interested in finding ways to use a wider range of donors, including older persons. Both Baldwin and Jamieson are interested in techniques to preserve the donor heart and lungs for longer periods outside the body.

"I believe one of our major recent accomplishments in the laboratory has been the ability to preserve the (delicate) tissues of the lung for up to six hours outside the body," Jamieson said.

New techniques developed in Stanford's cardiovascular surgery laboratories involve transporting the donor organs in solutions which have been developed to match the composition of the lung itself.

1-29-86

-more-

Transporting organs outside the body extends the geographic distance teams can travel to collect organs and "also helps solve some of the human relations issues involved with families, who may be reluctant to allow the body of a loved one to travel to another city for removal of vital organs," Baldwin said.

On the political front, Jamieson was vocal in supporting a recent California law which requires that families of potential donors be informed by hospital personnel of the procedures for allowing organs to be transplanted.

Baldwin is anxious to increase the uses of heart-lung transplantation but sees practical obstacles because of the donor shortage. Currently 15 persons are waiting for heart-lung donors at Stanford. Because of the donor shortage, the Stanford team has never been able to perform more than seven operations in a year.

To date, various birth defects causing heart and lung damage have accounted for 14 of the 29 patients who received the dual transplants at Stanford. The other patients suffered from a condition called primary pulmonary hypertension, in which the blood vessels in the lungs constrict. This causes breathing problems but also causes a damaging backup of blood into the heart. There is currently no known cure for the condition other than replacing both the heart and lungs.

Baldwin foresees the possibility of using heart-lung transplantation for other maladies, including perhaps cystic fibrosis, a congenital ailment which results in deterioration of the lungs. But Baldwin is even more encouraged that underlying research involving the program may lead directly to knowledge which would benefit cystic fibrosis patients without the need for transplantation.

"One aspect which has been noted in heart-lung patients who have suffered long-term rejection of their new organs is that the changes in lung tissue may resemble the damage that occurs in cystic fibrosis. This leads us to consider the possibility that cystic fibrosis might be studied as an autoimmune disease in which the body's immune system attacks itself. Antirejection drugs, which help the body to accept the donor organs, might someday be useful at treating cystic fibrosis patients."

Rejection and medication to prevent that phenomenon has been a major thrust of Stanford's transplant research. It was the pioneering work at Stanford and elsewhere on a new immunosuppressive drug, cyclosporine, which facilitated the first heart-lung operations at Stanford in 1981.

"Our very first concern," said Baldwin, "is our patients and what we do as physicians reflects this priority. But as the cystic fibrosis example indicates, the transplant program has given us a unique opportunity to study questions which otherwise we would not be able to explore."

The program has enabled the scientists to explore important but more general physiological questions. Jamieson notes that breathing and circulation are maintained without nerves connected to the heart and lungs, and this phenomenon has been useful for a variety of studies.

Baldwin said he decided to become a cardiovascular surgeon when as a Stanford medical student in the early 1970s, he served a student clerkship (training experience) under Shumway. After graduating in 1975, he completed residency at Massachusetts General Hospital in internal resident and subsequently in general surgery.

Baldwin said he decided to include internal medicine in his training after consulting with Shumway while still a medical student at Stanford. He credits this experience with providing "useful perspective in the postoperative management of patients."

Since returning from Boston to Stanford as chief resident in cardiac surgery in 1981, Baldwin has personally participated or served as primary surgeon in all but two of the 30 heart-lung transplant operations.

Baldwin, a Stanford staff member in cardiovascular and thoracic surgery since January 1984, was named assistant professor of cardiovascular surgery in 1985. He received his B.A. summa cum laude from Harvard University in 1971 before becoming a Rhodes Scholar in physiology at Oxford University in England. In addition to his transplant and cardiac surgery duties, Baldwin is an active thoracic surgeon. In 1985 he received the Gothenburg (Sweden) Thoracic Society Medal.

Jamieson, who has been a primary or secondary author of more than 200 professional journal papers during his eight years at Stanford, is a native of Rhodesia (now Zimbabwe). He was a 1971 graduate of the University of London Medical School. At Stanford, he was granted a tenured appointment as associate professor of cardiovascular surgery in September 1984.

In addition to his transplant and other cardiac surgery activities at Stanford, Jamieson has recently served as co-director of cardiovascular surgical services at the Palo Alto Veterans Administration Hospital.

QUENTIN M. GEIMAN, RETIRED TROPICAL DISEASE EXPERT, DIES AT 81

STANFORD—

Memorial services have been scheduled Friday (Jan. 31) for Quentin M. Geiman, Ph.D., an internationally recognized authority on tropical diseases and professor emeritus of preventive medicine at Stanford University Medical School.

Geiman, who retired in 1970, died in his sleep at his Los Altos home late Monday (Jan. 27) at the age of 81. Friends said he had suffered recently from ill-health but remained active in community senior citizen affairs until his death.

Dr. Count Gibson, chairman of the Department of Family, Community and Preventive Medicine (FCPM) and a colleague, said he planned to attend a civic meeting the evening of his death but told his wife of 55 years, Anne, he was tired and wished to rest.

"His greatest academic contibution was in encouraging and stimulating the interest of medical students and other faculty in the health of other nations," said Dr. Rodney Beard, a retired colleague who served as chairman of Geiman's department, preventive medicine, the predecessor of FCPM.

Geiman was perhaps best known as an authority on malaria and for directing a Tropical Health Training Program which awarded traveling fellowships to students interested in gaining experience in developing countries.

He directed a Parasite Diagnostic Laboratory at the Medical Center and served as a consultant to government agencies on diagnosing and handling parasitic infections in patients and the public. He traveled extensively throughout the world in connection with his research and consulting activities.

Geiman came to Stanford in 1955 after a 20-year career at Harvard Medical School and the Harvard School of Public Health. A native of Glen Rock, Penn., Geiman received his B.S. degree in 1927 from Gettysburg College in Pennsylvania. He received a master's degree in 1931 and a Ph.D. in 1934 in biology from the University of Pennsylvania.

In addition to his wife, Geiman is survived by a son, Rodney of Sunnyvale; a daughter, Carolyn Smith of Del Mar; a brother, Harry, of Pennsylvania; a sister, Ruth Geiman of Connecticut, and five grandchildren.

Friday's memorial service is scheduled at 2 p.m. at Spangler Mortuary in Los Altos. Memorial contributions may be made to the library fund of the Department of Family, Community and Preventive Medicine, c/o Dr. Count Gibson, Stanford Medical Center, Stanford, CA 94305.

VOLUNTEERS WITH MODERATE CHOLESTEROL SOUGHT FOR STANFORD STUDY

STANFORD—

Stanford researchers will be studying whether a drug widely used for 20 years to lower high cholesterol is equally effective at helping persons with moderate levels of fat in their bloodstream.

"High blood cholesterol is widely recognized by the American Heart Association as a major cause of coronary heart disease. Now the evidence is mounting that even persons with moderate levels of cholesterol can benefit from a program to improve this condition," said Dr. Robert Superko, medical director of Lipid Research Clinic of the Stanford Center for Research in Disease Prevention (SCRDP).

Superko and his team are looking for about 60 to 80 persons who have moderately high blood cholesterol to participate in a 16-week trial of the drug colestipol.

Superko said the volunteers should have levels of cholesterol (about 220 to 265 mg/dl) which traditionally are treated by diet but not medication.

"We're talking about a large group of the population, perhaps as many as 30 percent of the Bay Area population (whose cholesterol level would qualify them as potential participants). These are persons who by lowering their blood cholesterol below about 200 can reduce their risk of heart attack by approximately 20 percent," Superko explained.

Although colestipol has been prescribed since the 1960s to persons with extremely high cholesterol levels, generally in access of about 270 mg/dl, "it is only in the last few years that the evidence indicates that persons with moderate levels can significantly benefit from blood cholesterol reduction," Superko said.

Colestipol removes a damaging component of blood cholesterol, low density lipoproteins (LDL), from the body by enhancing the liver's ability to remove LDL from the blood. The drug is a bile acid binding resin.

Certain components of cholesterol, essentially fat molecules such as LDL, are dangerous because they attach themselves to the interior of blood vessels, causing reduced arterial blood flow, potential blockage of arteries and ultimately heart attacks as total blockage occurs and/or the heart muscle becomes damaged.

The researcher noted that areas of Asia where the average LDL cholesterol level is about 110, coronary artery disease is virtually nonexistent. "Diets which are low in saturated fats help most people to reduce their cholesterol. But for some people such a diet is impractical, and for other people, genetic and other health factors preclude them from using diet alone to lower their cholesterol," Superko said.

In the current study, half of the volunteers will take the Food and Drug Administration-approved medication in doses smaller than customarily given to persons with severely high levels of cholesterol.

The remainder of the volunteers will be in a control group and will take a placebo, an inert substance which looks and tastes like colestipol.

The volunteers will receive the medication, periodic testing for blood cholesterol level, and general cardiac health information at no cost, Superko said. He said colestipol has proven to be extremely safe. Potential side effects can include minor gastrointestinal discomfort.

Persons interested in volunteering should contact Pamela or Paula at (415) 497-6254 between 1:30 and 5 p.m. on weekdays. Dr. William Haskell, deputy director of SCRDP, is principal investigator for the project. Superko is medical director.

GEORGETOWN CARDIOLOGIST VISITS STANFORD AS FIRST SHENSON VISITING PROFESSOR OF MEDICINE

STANFORD—

Dr. Proctor Harvey, a renowned cardiologist and professor of medicine at Georgetown University School of Medicine, will be at Stanford for the month of February as the first Drs. Ben and A. Jess Shenson Visiting Professor of Medicine.

The professorship was established last spring by the Shenson brothers, both of whom received their undergraduate and medical degrees at Stanford, in memory of their parents, Louis and Rose Shenson.

Harvey will present a number of lectures, conferences, seminars and meetings during his visit, including the department of medicine's grand rounds on Feb. 13. The title of his presentation, to be held in Fairchild Auditorium, is "Cardiac Pearls."

Harvey has been on the Georgetown faculty since 1950. Throughout his career he has been actively involved in professional organizations and has held editorial positions on several cardiology journals. He has received numerous honors for his clinical and teaching excellence, the latest of which was for an exhibit, "W. Proctor Harvey Textboxes of Cardiology," at the 1985 American College of Cardiology meeting.

Harvey will have an office in the cardiovascular research building, room 156, and can be reached at 497-6141.

The Shensons have practiced internal medicine in San Francisco for more than 30 years. They served on the clinical faculty of the medical school in San Francisco as well as in Palo Alto.

The Shensons have been active financial supporters of Stanford. They established a medical student loan fund in honor of their parents in 1950. They have a strong interest in the arts, particularly the opera. They have also patronized the work of early California artist Theodore Wores.

STANFORD PHYSICIAN SHATTER KIDNEY STONES WITH SHOCK WAVES

STANFORD—

A new, non-invasive technique that shatters kidney stones with shock waves is now available to Stanford urology clinic patients through a unique collaboration with the Los Gatos-based Northern California Kidney Stone Center.

The center was established nearly a year ago by Stanford medical school alumni Drs. Kersten Kraft and Robert Dale and operates under the medical direction of Stanford urology professor Dr. Duncan Govan.

The physicians at the center, the only facility of its kind not located in a hospital, have blasted kidney stones using extracorporeal shock wave lithotripsy in more than 550 patients since it opened.

Kidney stones, most commonly composed of calcium deposits, affect about one of every 10 American adults. If the stones are small enough, the body eliminates them along with urine. For as many as 30 percent of those who have kidney stones, however, this does not happen. Too big to pass through the uretha, the stones can be a source of infection, obstruction and extreme pain, Dale explained.

Until now, physicians have had to surgically remove kidney stones, a procedure that entails prolonged hospitalization and recuperation times for the patients. With lithotripsy however, patients recline in a tub of warm water instead of laying on an operating table. The non-invasive procedure takes about an hour, and a few days later most patients are back to work and their regular activities.

"People want to eliminate kidney stones mostly because of the pain they're causing, or the fear of it," Dale said. "Some professionals, such as pilots, are not allowed to work if they have kidney stones." The pain is so intense, he explained, it might compromise their ability to fly.

The outpatient facility enables most patients to save time and money by avoiding hospitalization, Kraft said. Even so, the cost of the treatment is upwards of $7,000. In establishing the facility, the physicians wanted to create a center that physicians from all hospitals in the area could send patients to rather than limit access by having the machine in a specific hospital. The lithotripter machine is expensive--nearly $2 million for purchase and installation--and they saw no need for its unnecessary proliferation.

The center attracts patients from all over the region and bordering states. Stanford urology residents train there as well.

1-30-86

-more-

To undergo treatment, patients under general anesthesia are immersed in the warm bath in a reclining position. An electrode on the bottom of the tub is responsible for emitting sparks that cause the shock waves. Physicians can precisely pinpoint the location of the kidney stones with the aid of X rays and then position the patients so that the stones are in direct line of the force of the shock waves. Up to 3,000 shock waves are produced during a treatment, each passing harmlessly through tissue to unleash its force on the stones. Physicians can watch computer screens that show the stones being shattered into fine sand-like particles.

"Patients are put under general anesthesia because the procedure is very painful," Kraft said. "Imagine being slapped on your back as hard as possible thousands of times. That's what it would feel like."

But, other than being bruised by the "slaps," many patients experience no side effects. After waking up from the anesthesia, which takes an hour or two, patients can rest at home for a couple of days and then resume regular activities. An estimated 80 percent of the patients need only one treatment to rid them of their stones.

"We found that 50 percent of the patients have no pain following lithotripsy," Kraft said. "About 25 percent experience minor pain and another 25 percent experience major pain."

About 20 percent of the patients, he continued, need a brief hospitalization following treatment. Complications can arise from the anesthesia, or if the patient has only one functioning kidney, other health problems such as asthma or heart disease, or if the stones were particularly complex. Nonetheless, the physicians feel they have a pretty good track record."After all, this is an operation," Kraft emphasized.

Kraft and Dale began researching lithotripsy after they heard a speaker from Germany describe the technique at a medical meeting in 1981. After the Federal Food and Drug Administration approved the lithotripter for import into the United States in 1984, they started vying for a machine, all of which they assumed would go to academic medical centers. Dr. Thomas Stamey, head of Stanford's urology division, lent his support to their efforts and to seal the relationship. Govan was appointed medical director. Dr. George Duecker, another Stanford alumnus, also joined the team. When the German manufacturer selected the first 10 groups to purchase a lithotripter, the center was the only one named in Northern California (the only other machine in California went to University of California, Los Angeles).

Since then, University of California, San Francisco, and Los Gatos Community Hospital have purchased lithotripters. But, Kraft said, "there's something to be said for being the first."

STANFORD'S KEY ROLE IN STATE SCREENING PROGRAM FOR PREGNANT WOMEN

STANFORD—

The state of California is about to start a major new program to screen pregnant women for signs of neural tube defects in their fetuses, and Stanford University Medical Center will play a key role in the program.

Neural tube defects, abnormalities of the spine and skull that can cause severe lifelong medical problems or result in death in infancy, are present in approximately 1 in 1,000 births. They can be detected about 85 percent of the time by a simple test to determine the level of alpha fetoprotein in the mother's blood.

California will start a statewide campaign in the next two or three weeks with the goal of making the screening available to all women in the state between the 15th and 20th week of pregnancy.

Stanford's role in the campaign is twofold:

- It is the headquarters of the genetic counselors coordinating the program in the five counties of Santa Clara, Santa Cruz, Monterey, San Benito and San Luis Obispo.
- It will be one of the diagnostic centers for follow-up procedures necessary if the blood tests are positive (a positive blood test is not a certain diagnosis of neural tube defects).

Although pilot programs of alpha fetoprotein screening have been conducted in other states, California's is the largest so far in the United States. It is to be offered to all pregnant women in the state, but participation is voluntary.

The screening fee is $40, which will be paid by most medical insurance plans and MediCal. That will take care of the initial blood test, which can be taken in a clinician's office, and it will also pay for any further authorized tests—such as amniocentesis or ultrasound—that might be necessary at diagnostic centers such as Stanford. The program is designed to be self-supporting and no tax money will be involved.

Blood samples will be sent to one of several large laboratories throughout the state and the results will be returned to the clinician. In about 92 percent of the cases, the results will indicate no problem. But even in the cases where there is a positive result, it doesn't necessarily mean a neural tube defect. It merely means the woman will have to undergo repeat testing for alpha fetoprotein and possibly ultrasound or amniocentesis.

Cindy Soliday is the coordinator of the program operating out of the genetic counseling clinic of the department of gynecology and obstetrics of the Stanford Medical Center. She emphasized that the test is not 100 percent accurate as far as negative results go, either. "Patients really need to understand," she said, "that if they take the blood test and they get back a normal result, it's not necessarily guaranteed that there's not a neural tube defect because there is a false negative rate."

2-25-86

-more-

If the blood test and further tests with ultrasound and amniocentisis do show a neural tube defect, parents are faced with an agonizing decision. About half of neural tube defects involve anencephaly, which means the incomplete formation of brain and skull; almost half involve spina bifida, defective closure of the spinal cord encasement; and about 5 percent involve encephalocele, a bony defect of the skull that can be accompanied by brain involvement.

At that point, a decision on whether to terminate or continue the pregnancy is left entirely up to the parents, but at least they will be aware of the problem before birth.

There were 435,000 births in California in 1983, the last year for which figures are available. On the basis of 1 in 1,000 being neural tube defects, that means the testing program would detect approximately 435 fetuses with the defect if all the pregnant women in the state could be included in the program.

Soliday said that sometimes the test will pick up other birth defects, such as Down's Syndrome, but most abnormalities of that order will not be detected.

Up to now Soliday and Linda Whipperman, who is also working out of Stanford under a state grant setting up the program, have been concentrating on informing doctors and hospital employees in their five-county area about the program. But the state will soon be ready to begin educating the public and they will help in the program of information and education.

Dr. Luigi Luzzatti and Dr. James E. Ferguson II are co-directors of the screening program at Stanford.

Once the program is under way, Soliday said, she will monitor the results in her five-county area. Although the laboratories will return test results directly to the doctors and hospitals, Soliday will be hooked up to the state system by computer and will get a list of the positive results in her area.

"My responsibility will be to call the clinician and inform him or her in advance of the written notification so they can be timely in recommending follow-up procedures," she said. "Then we can help the physician or midwife or whomever's case it is with referrals, getting them hooked up to the right places, answering patients' questions if necessary."

LEACH APPOINTED CHAIRMAN OF FRIENDS OF RADIOLOGY

STANFORD—

Frank Leach, a leader in the corporate community and resident of Woodside, has been appointed chairman of Stanford University Medical Center's Friends of Radiology.

Leach, chairman of Pollock Financial Corporation and Acme Fixture Company, began his new responsibilities Feb. 19. He succeeds Keith Erdman, chairman of the philanthropic organization since 1978.

The group, which includes about 3,500 members nationwide, raises as much as $500,000 each year to help support the research and clinical activities of Stanford's radiology department. Current projects include raising $1 million for a magnetic resonance imaging machine and funding cancer research by Stanford faculty.

Leach, who was successfully treated at Stanford for cancer, has been actively involved with the group since 1983. One of his goals as chairman, he says, is to continue to broaden the membership of the group. "It's especially important to continue our support in this time of funding cutbacks," he said.

"We are fortunate to have someone with his leadership position to call upon," said department chairman Dr. Malcolm Bagshaw. "With Leach serving as chairman, the Friends of Radiology will be in good hands."

ALCOHOLICS NEED INDIVIDUALIZED TREATMENT, RESEARCHERS SAY

STANFORD—

The treatment of alcoholism must be more flexible than in the past and must be measured carefully for effectiveness, according to the co-directors of Stanford's new alcohol and drug treatment center.

Dr. Robert A. Matano and Dr. William Hazle, who structured Stanford's recent second annual conference on alcoholism around that theme, have built Stanford's new unit on those principles as well.

Already accepting outpatients, the Stanford unit features short-term detoxification and long-term, well-organized outpatient counseling and medical care. Official opening of the unit, a joint arrangement between the hospital and the department of psychiatry, is expected in about a month.

"We're seeing that the cookie cutter approach of the past may not have been as effective," said Matano, psychologist and program director of the Stanford center.

Alcohol treatment programs previously have been shaped more by reimbursement policies than by medicine, Matano maintained.

"The treatment of alcoholism currently lacks the core scientific base common to other areas of medicine," agreed Hazle, the psychiatrist who is medical director of Stanford's alcohol clinic,

As a social disgrace, alcoholism was shunned by mainline society—including medicine. Treatment of the disease was left to organizations such as Alcoholics Anonymous and the Salvation Army, Hazel explained, "and only now is the science beginning to catch up."

Statistics presented during the day-long conference "Evaluating the Effectiveness of Alcohol and Drug Treatment" on Feb. 14 supported the Stanford researchers' views.

"We need to realize that (patients') life context affects everything," Dr. John Finney told the 140 physicians, therapists, and employee assistance personnel attending the Stanford conference.

Family status, work settings, life stresses, socio-demographic factors and personality all affect treatment outcome and must be taken into account, said Finney, a research associate in the department of psychiatry and behavioral sciences at the Veterans' Administration Medical Center in Palo Alto.

"We need a more differentiated view of treatment," he said, stressing that many factors must be monitored and recorded in order to evaluate programs seeking to rehabilitate alcoholics.

Dr. Joseph Frawley, medical director of the Schick Shadel Hospital in southern California, agreed.

"Before we can establish treatment," he said, "we have to come to a prognostic idea of how well an individual will do."

"Knowing the reasonable outcome is a part of the standard treatment of any disease," including alcoholism, he continued.

Drawing parallels between treating an alcoholic and rehabilitating a patient who has had a stroke, he called for greater precision in recording alcohol-related complications as an aid to patients' recovery.

Gauging a patient's alcohol consumption is tricky, but necessary, said Dr. Lorraine Midanik, assistant professor at the University of California, Berkeley's school of social welfare.

Midanik urged those who treat alcoholics to try to determine the individual's drinking pattern.

"Don't ask only what quantity they drink," she said,"but how it affects the person's life." More accurate questions, such as asking about the most alcohol consumed in a single incident and the frequency of drinking, will help establish a pattern, Midanik stated.

But predicting the damage alcohol will do is difficult, observed Dr. Kevin Olden as he detailed the impact of medical problems on the recovery process. Amounts that cripple some people may leave others virtually unscathed.

-more-

For example, neither nutritional status, drinking patterns nor type of alcohol abused affect development of alcoholic cirrhosis, noted Olden, medical director of the Pacific Recovery Center.

Cirrhosis, the most common medical complication of alcohol abuse, is irreversible damage to the liver. This form of liver damage often accumulates without warning until it is deadly, and is almost always attributable to substance abuse.

"Alcoholic cirrhosis could well be the leading cause of death in the future," Olden warned, especially "as we continue to make inroads against heart disease and cancer."

Accidents, homicide and other traumatic events are another major cause of death in alcoholics, especially in young abusers who have not yet developed other medical problems. A history of repeated accidents should prompt physicians to ask about substance abuse, Olden stated.

Dr. Stephanie Brown, program consultant to Stanford's Alcohol Clinic, took that thought even further. Every therapist and physician should assume alcoholism in each patient unless it's ruled out, she said.

"You must be looking to discover whether alcohol has become the major, centralizing factor in a patient's—or family's—life."

In order to recover, alcoholics must hit bottom and undergo a "basic change in their core identity," she said as she explained her new model illustrating the stages of alcoholism and recovery.

Recovery is an untidy process, she stressed. Alcoholics will go through certain stages as they recover, but the process is full of relapses and advances. "There are no formulas here," she admitted.

Therapists—historically opposed to the spiritual aspect of Alcoholics Anonymous (AA)—must accept and support AA's methods, according to Brown. Many alcoholics want traditional psychotherapy but fear that therapists will strip away or undercut their AA program and spirituality. Therapists, patients and AA must act as a partnership, Brown maintained.

Hostility between AA and medicine springs from differences in their wording, suggested Dr. Tony Radcliffe. "It's like interpreting two languages," he said, crediting Brown with presenting a successful translation.

Radcliffe established a substance abuse program for the Kaiser health maintenance organization in Southern California in 1979. Treatment for addiction to any mind-altering drug, including cigarettes, is available through the Kaiser unit.

The Kaiser program has seen the median age of patients drop from 57 to 33 years old in a seven-year period. Patients who have abused more than one drug are also more common, Radcliffe noted.

America is one of the top three nations in the world with a per capita problem with mind-altering drugs, Radcliffe stated.

Experts estimate that there are more than 14 million alcoholics in America. Those individuals directly affect at least 56 million more, however, escalating alcohol's already heavy toll.

"Alcoholics don't have relationships: they take hostages," Dr. Timothy Cermak said dryly.

Cermak, himself the child of an alcoholic, studied at Stanford under Stephanie Brown, a pioneer in treating adult children of alcoholics. Now an assistant clinical professor of psychiatry at the University of California, San Francisco, Cermak also is founder of a national organization for adult children of alcoholics.

Problems may lie hidden for years and may masquerade as other disorders, Cermak cautioned, encouraging therapists to ask patients about substance-abusing parents. Adult children from substance abusing homes are more likely to seek therapy than the general public, he noted.

Those with alcoholic parents may show signs of post-traumatic stress similar to that suffered by Vietnam veterans, according to Cermak. A great rupture between these individual's feelings and their consciousnesses has occurred and must be brought out in order to be healed.

Therapists must use different approaches with alcoholics themselves than with their adult children, Cermak recommended.

Counseling for adult children of alcoholics is available through Stanford's alcohol clinic. Phone (415) 497-6682 or 6683.

A SPECIAL KIND OF NURSING CARE HELPS A SPECIAL PATIENT

STANFORD—

Al Perez had his birthday party last week in a room at the East Intensive Care Unit at Stanford University Hospital—a hospital room decorated with 120 balloons and featuring the smell of Chinese food.

It was a hastily arranged party, because the nurses who organized it had just learned that Perez was being transferred the next day to Santa Clara Valley Medical Center in San Jose. Originally, the party had been scheduled for Feb. 19, Perez's 32nd birthday, and it was to be a joint celebration with his wife, Maria, and with the three primary care nurses who have been at Perez's side almost constantly since he entered Stanford last September. All of them, coincidentally, share February as a birthday month.

Perez smiled a lot at his birthday party, but he couldn't do much more to show his appreciation. The accident that brought him to Stanford last September crushed his spinal cord at the neck and he has been a quadriplegic ever since.

However, he has made progress. At first, it was feared he wouldn't live—or wouldn't want to live; that his mind or vision might be impaired; or that he wouldn't be able to eat.

All of those obstacles have been overcome. He has survived, he has made it clear to his wife that he wants to live, his mind and vision are clear and he can eat anything he wants.

That progress is a source of pride and joy to the three primary care nurses who have almost become family members of Perez during his stay at Stanford. The nurses—Mary Hafey, Ray Martel and Linda Thompson—all feel certain that Perez has been helped by the fact that he has had familiar faces taking care of him day after day.

"We think that having the same nurse over and over again and doing the same things tends to help a person," said Hafey.

"When you do primary care the big thing is that you oversee that all the things he needs are done appropriately to his liking," Martel said. "But the biggest thing is psycho-social; we are really his support for the day."

Thompson elaborated on that: "We were able to get close enough to him to make a difference. He was able to open up to us."

It wasn't just Perez; his entire family needed support. As Thompson said: "You're not just treating a patient in crisis. You're treating a whole family in crisis."

In Perez's case, that was a large family indeed. He is one of 11 brothers and sisters and his parents are both still living. Then there are his wife and three young children.

Most of the family members live in San Jose, where Perez has his home. They had great difficulty accepting his accident, because he had been exceptionally vigorous and active before. He had worked as a teacher and insurance salesman and at one time had been a member of the San Jose Police Department. He also had been an active soccer player and was a volunteer counselor for youths in drug rehabilitation programs.

"They were always hoping for a miracle," Hafey said of the Perez family. "It was a long time before they were convinced that he would never move again."

Martel sees the miracle as "not necessarily being that he walk and that he's up but rather that Al be given a chance to be alive, which was really in question when he arrived. And through nursing and the work that we did we brought the world to him or him to the world so that he is alive and he can communicate and he can do some things. Al can still function with his mind and that's the big thing."

Now, Hafey said, the Perez family members "are like good friends, almost like family." And Martel said, "The family has fed back to us that we are the miracle they were looking for. That's the best reward you can get on the job, to know that these people feel good about the nurses that are taking care of him."

It was far more than just "taking care," of course. For example, there was Christmas, as Hafey described it:

"We asked if he'd like to get Maria something for Christmas, and brought in some catalogs and magazines for him to look at. He knew right away what he wanted; he wanted to give her a necklace with a heart and a little diamond in it.

"So we took up a collection and we were able to get her necklace. On Christmas morning we put it in his hand. When she came in, he mouthed the words to her, 'touch my hand.' She couldn't understand him at first so he had to use his alphabet board to write it out. Then finally she got the point and touched his hand and then she saw this little box. She was very touched."

The alphabet board mentioned in that account is a device the nurses have worked out with Perez to help him communicate. They hold up the lines of letters, he opens his mouth at the correct letter and they write it down. The board is set up in lines and Perez has the lines memorized, so the system can be reasonably fast.

All of the nurses have many touching stories to recount involving the Perez family. Hafey recalls hearing one of his daughters tell Perez: "Daddy, we need you to come home because we're afraid. The other night there was a noise and we didn't know what it was and we wished that our dad was there. We need you to protect us."

Those strong family ties undoubtedly have helped Perez's recovery and they should help at Valley Medical Center, where he and the family will undergo rehabilitation training in preparation for his return home.

At home, of course, he will need even more help from his family members as they fill the roles now handled by the nurses.

Hafey, Martel and Thompson have a total of about 40 years in nursing, almost 20 of them in Stanford's ICU. They all prefer ICU work for the same basic reason: the opportunity for personalized nursing, taking care of the needs of one or two patients and getting involved with them more intensely.

They are all pleased to see Perez ready for the next step in rehabilitation, but they admit to feeling sad at seeing a close friend leave.

And they make it clear that for all the help they gave Perez, they got a lot back in return. As Thompson put it: "Al's been a real inspiration to me. He's a special guy."

$1 MILLION TO SUPPORT NEW MOLECULAR MEDICINE CENTER AND CANCER RESEARCH LAB

STANFORD—

Stanford University has received $1 million from the Agnes Axtell Moule Medical Research Foundation to support the proposed Center for Molecular and Genetic Medicine (CMGM) at Stanford University School of Medicine, according to a report heard February 11 by the Stanford University Board of Trustees.

The $1 million amount is a portion of a bequest to the University valued at a little more than $4 million from the estate of Manley Moule, who died in 1974.

The remaining $3 million in the bequest also has been designated to help build and equip CMGM, which will include a cancer research laboratory to be known as The Agnes Axtell Moule Laboratories for Cancer Biology Research, the report said.

Moule, who was a 1917 graduate of Stanford, intended the funds to be used for medical research and/or building and equipping a medical research laboratory.

Prior to his death, he was involved in real estate with the W. Ross Campbell Co. in Los Angeles. The new laboratory within CMGM will be a memorial to his mother, who died of cancer in Palo Alto in 1939.

The Moule Medical Research Foundation has held the Moule bequest to the University since 1975. Income from the endowment has funded research fellowships for junior faculty members at the Medical School.

GONDA APPOINTED TO HOWARD ROBBINS PROFESSORSHIP IN PSYCHIATRY

STANFORD—

Dr. Thomas A. Gonda was appointed The Howard C. Robbins Professor of Psychiatry and Behavioral Sciences in the School of Medicine by the Stanford University board of trustees at its February 11 meeting.

The Howard C. Robbins Professorship, established in 1985 by a gift from an anonymous donor, honors Howard C. Robbins, M.D., a Cornell University Medical School graduate who joined the Stanford Medical School psychiatry department's clinical faculty in 1962.

Gonda, who has been a Stanford faculty member for more than 30 years, has served as professor and chairman of the psychiatry department since 1974.

He is widely recognized for scholarly research relating to the link between behavior and the central nervous system, medical jurisprudence, pain and its relation to terminal illness, and psychological and social issues related to treatment of the dying and the bereaved.

Gonda earned both his bachelor's and medical degrees from Stanford University in the 1940s, joined the faculty in 1953, and became full professor in 1965.

In addition to his long tenure as psychiatry department chairman, Gonda has held several other key administrative posts at the medical center, including associate dean of the medical school from 1967-74, and director of Stanford University Hospital from 1968-74.

He is the recipient of a number of awards including a 1983 Life Fellowship Medal from the American Psychiatric Association, and a 1984 Outstanding Achievement Award from the Northern California Psychiatric Society.

His widely praised 1984 book, *Dying Dignified: the Health Professional's Guide to Care*, was named the outstanding book for nurses by *Nursing '84* magazine and "book of the year" by the *American Journal of Nursing*.

Dr. Robbins, who is now clinical associate professor emeritus, graduated from Ursinus College in 1933, received an M.A. in psychology from Columbia University in 1936 and gained his M.D. from Cornell in 1940. He served as a flight surgeon in the Army Air Force from 1941 to 1945.

As a tribute to Dr. Robbins, the professorship is to be held by a member of the Department of Psychiatry and Behavioral Sciences who is engaged in studies to advance the field of psychiatry.

RAYCHEM'S HALPERIN NAMED TO STANFORD HOSPITAL BOARD

STANFORD—

Robert M. Halperin, president and chief operating officer of Raychem Corp. of Menlo Park, has been appointed to the Stanford University Hospital Board of Directors.

He was selected by the general members of the Hospital corporation to complete the unexpired term of Nancy Barry Munger. The term runs until Dec. 31, 1987.

The 18-member hospital board is comprised of community, medical and lay leaders as well as university faculty and administrators. Twelve of the members are appointed by the general members of the Hospital corporation, who also are trustees of the university.

Halperin, 57, joined Raychem in mid-1957, a few months after the company was founded. He is also a member of the board of directors of Molecular Design, Ltd., a trustee of the University of Chicago and chairman of the university's visiting committee to the division of physical sciences. He is a member of the Stanford University Athletic Board.

A native of Chicago, Halperin earned a bachelor's degree in liberal arts from the University of Chicago and another in mechanical engineering from Cornell University, both in 1949. He received a master's degree in business administration from Harvard University in 1952.

He was a lieutenant in the U.S. Air Force during the Korean War.

STANFORD HOSPITAL BEGINS FUNCTIONING AS TRAUMA CENTER

STANFORD—

Stanford University Hospital began operation as a trauma center last Saturday morning, eight months after the hospital began preparations for the role.

An official contract designating the hospital as one of three Santa Clara County trauma centers was signed Tuesday, Feb. 11, after hospital officials and Santa Clara County supervisors agreed on contract language.

Approval of the contract had been considered just a formality once Stanford was approved for the trauma center designation by an evaluation team in December.

San Jose Hospital and Valley Medical Center have also been approved as trauma centers for the county, meaning that critically injured patients throughout the county will be brought to one of the three hospitals. County officials estimate there are about 1,300 patients who require such treatment each year.

Concentration of trauma treatment services in a limited number of hospitals is expected to save both lives and money. The trauma centers will get enough patients to make the extra costs of trauma treatment financially feasible and the trauma teams will see enough critically injured patients to maintain their skills.

It has been estimated that trauma centers would have prevented 73 traffic deaths in the Bay Area in one year.

PANEL TO DISCUSS MEETING MEDICAL NEEDS OF POOR

STANFORD—

Three directors of large medical organizations and a California state senator with a wide background in mental health will discuss "New Challenges for Public Service: Meeting the Medical Needs of the Poor" at a workshop Saturday, Feb. 22, at Stanford University.

The workshop, scheduled at 1:45 p.m. in the Graduate School of Business, is part of a day-long conference called "You Can Make a Difference: Private Initiatives and Public Responsibilities."

Panelists at the medical needs workshop will focus debate on a topic paragraph:

"For two decades public concern for equal access to medical services for all citizens has dominated changes in public policy. When Medicaid passed in California, the theme was 'Mainstream Medical Care' and the elimination of the county hospital or 'dual level of care system.' Cutbacks in health services in recent years are forcing the poor back into the county hospitals and placing other segments of society—among them the elderly—at financial and clinical risk. Can the health system address these questions or should the answers be given by the total society?"

The workshop panelists are:

State Sen. Dan McCorquodale, D-San Jose, a former member of the Santa Clara County Board of Supervisors. He chairs the Senate Subcommittee on Mental Health, Developmental Disabilities and Genetic Diseases and is a member of the Health and Human Services Committee and the Subcommittee on Health Care Cost Management.

Carol B. Emmott, executive director of the California Association of Public Hospitals, an organization headquartered in San Mateo that includes 22 of the state's largest county hospitals. She has been deputy director for policy and program support in the San Francisco Health Department and a special assistant in the U.S. Department of Health, Education and Welfare.

Dr. Ralph W. Schaffarzick of Burlingame, senior vice president and medical director of Blue Shield of California. He received his bachelor's degree and his M.D. from Stanford and is a clinical professor of medicine at the Stanford School of Medicine. He has served on a dozen state and local medical advisory committees.

Clifford U. Portis, executive/project director of the San Francisco Medical Center Outpatient Improvement Program, Inc. He directs the activities of three community health centers providing primary care to approximately 75,000 persons. For six years prior to accepting his present job, he was assistant director of hospitals and clinics for the University of California-San Francisco.

HUMAN GENE THERAPY MAY BE ON THE HORIZON BUT IT IS NOT IMMINENT, SCIENTISTS SAY

STANFORD—

The dramatic swing between optimism and pessimism — among scientists' attitudes towards human gene therapy — took a turn for the latter at an all day media round table on gene therapy held at Stanford Thursday, Feb. 13.

Human gene therapy is a technique for treating genetic diseases, such as diabetes and sickle-cell anemia. It involves transplantation of good genes to do the work of defective ones.

Recent experiments in animals have proved to scientists that, in theory, gene therapy is simple, but in practice it is very complex and it may take weeks, months, or even years before it will be a viable treatment for human disease, according to Paul Berg, Stanford professor of biochemistry and a 1980 Nobel Laureate, who gave the opening comments at the conferece.

The purpose of the conference, sponsored by Scientists' Institute for Public Information, the American Association for the Advancement of Science, and the Association of American Universities, was to inform journalists about human gene therapy. The morning session was devoted to the science of gene therapy while the afternoon session covered ethics and policy of gene therapy.

Previous success in experiments on insects and mice had made scientists optimistic, but more recent experiments in monkeys show that there maybe something that turns off foreign genes in live animal experiments, that is not seen in test tube experiments.

This new stumbling block has made some scientists more pessimistic, according to W. French Anderson, chief of the Laboratory of Molecular Hematology at the National Heart, Lung and Blood Institute.

In Berg's lab, researchers "are trying to repair the old gene by introducing the normal gene sequence and trying to promote repair of the defective gene." This is the situation that is closest to normal, he said.

The scientists made it clear that the gene therapy they were discussing included manipulation of the genes in somatic (body) cells, not germ line (reproductive) cells which effect future generations.

Gene therapy today is only at experimental stages and is not federally approved for use on humans, but many scientists see its potential for curing the 3-4,000 known genetic diseases of which there are currently no cures and only poor treatments.

"With this marriage of molecular biology and medicine, something is going to be born and 'this child' is going to be a genetic attack at disease, something that is conceptually new and in a way revolutionary," said Theodore Friedmann, professor of pediatrics at University of California at San Diego.

But according to David Cox, associate professor of pediatrics at University of California at San Francisco, in order for gene therapy to be approved for use on humans, in general, "the probable benefits have to outweigh the probable risks."

A more imminent "reality" of "modern gene technology, is the ability to isolate genes," for early diagnosis of genetic diseases, according to Berg.

With some diseases, based on DNA analysis "it is possible to determine if an individual has a normal, abnormal, or modified form of any particular gene that has been isolated and identified, according to Berg. It can be done "at a very early stage in development, perhaps as early as the 8 week of pregnancy," he said.

2-18-86

-more-

Thus, with some genetic diseases "there is at least one option of treatment and that is to abort the fetus," he said. Given a choice of raising a child with a severe congenital disease or aborting a fetus and conceiving another, it is Berg's impression that most people would elect abortion, he said.

However, according to Nancy Wexler, from the Hereditary Disease Foundation, "some people say my brother has that disease, therefore how could I abort 'my brother,' but I also hear kids saying I wish I had never been born."

"It is not theoretical anymore, everybody is going to have to face these questions," she said.

If funding does not continue for research we will be stuck with the consequences of "the power to predict, but not the power to prevent (disease); we have a certain responsibility to carry on research," she said.

But, "funds for research are becoming increasingly constricted at the very time that people are having the best ideas," she said.

Berg said, currently "there is an enormous frenzied activity (in research) all over the world in trying to fill in the details about how all the genes work."

"All human disease in fact has a genetic component; a chromosomal abnormality is a genetic disease," he said. For "the largest number of (diseases) we don't know either the genes or the number of genes that are involved in producing a particular disease symptomatology."

"The next step for ultimately doing (gene therapy) in patients is to go into primates and primate cells and to chose a human disease that is the most likely candidate," said Anderson. And ADA (adenosine deaminase) deficiency is the chosen disease, he said.

This rare disease is brought on by lack of an enzyme which leads to severe disabling of the body's immune system, and death by infection around the age of two, Anderson said.

Scientists are currently working on developing gene therapy to cure ADA deficiency because it is a disease caused by a single gene defect and it occurs in the blood which is more accessible to doctors than a kindney or a liver is, for example.

"If gene therapy doesn't work for ADA deficiency it is probably not going to work for anything," Anderson said.

"Now, the most likely place for advances (in treatment of genetic diseases) is in organ transplant," he said. ADA deficiency can be cured through bone marrow transplant if there is perfect tissue match between graft and host, he said.

Friedmann said, "we are all convinced that the science of tissue transplantation is on the verge of rather major improvements and developments," which could make bone marrow transplants the treatment of choice.

Yvonne Baskin, free-lance science writer, said that people's apprehensions about gene therapy are sort of "a mystical feeling about genes."

And, according to Anderson people's apprehensions are valid because "we don't really know what makes us human" and people think that scientists may be interfering with something that they don't really know about, he said.

Other conference participants include: Robert Cook-Deegan, Office of Technology Assessment, U.S. Congress; Eric Jungst, University of California at San Francisco division of medical ethics; moderator Laurie Garrett, science reporter, National Public Radio; Dave Perlman, associate editor and science editor at the San Francisco Chronicle; James Risser, director of the John S. Knight Fellowship Program at Stanford; and Knight fellow Linda Herskowitz, on leave from the Philadelphia Inquirer.

EXECUTIVES PLOT STRATEGIES FOR MANAGING CORPORATE HEALTH CARE COSTS

STANFORD—

Bay Area corporations are likely to attempt to have employees share more of the costs of health care in the future, and they'll stress "wellness" programs aimed at keeping employees healthy.

At least, those two areas emerged as prime considerations for reducing health care costs in strategies devised by some 40 executives attending a symposium co-sponsored by Saga Corp. and Stanford University Hospital.

The day-long symposium, held at Saga Thursday, Feb. 13, emphasized a "partnership approach" to the problem of rising medical costs. After health care authorities addressed several aspects of the problem, the participants broke up into small groups to work on the cost-management strategies at the end of the program.

Since the participants were just making suggestions without any constraints as to practicality, there were a great many ideas for controlling health care costs. But the wellness and cost-sharing themes turned up repeatedly. Other popular ideas were for better communications with employees—and with management—and for putting limits on the amount of treatment an employee's dependents could receive for drug-related problems.

The participants were also asked to pinpoint areas in which health care cost management has made progress and areas in which there is a lot of room for improvement.

Most agreed that there has been a considerable improvement in public awareness of the rising costs and a realization that something must be done. They also thought the growth of alternative delivery systems such as health maintenance organizations was beneficial.

Among the major continuing problems, in the views of the participants, are the oversupplies—or poor distribution— of physicians and of hospital beds.

Speakers earlier in the day included Sheldon King, president and chief executive officer of Stanford Hospital; William Arnold, executive vice president and chief operating officer of the hospital; Daniel Brunner, president of Affordable Health Care Concepts of Sacramento; and Chuck Fuhrman, manager of human resources for the White Paper Division of Boise Cascade.

King discussed "The Reality of Health Care Costs Today," pointing out that the health care field is in for an extended period of no growth or very limited growth.

He also noted that "a return to a second system of health care for the poor is emerging" because of government limits on medical aid.

Despite the current problems, King said, hospitals in general continue to make money, with their net income up approximately two percent. But he noted that there are regional differences in hospital situations and those in some areas, particularly smaller hospitals, "are in real difficulty."

2-18-86

-more-

Arnold outlined some of the steps Stanford Hospital is taking to become more competitive. After the budget cuts this spring, he said, "we will emerge leaner and much more aggressive in terms of the market place."

Discussing the downsizing, he said, "We're writing the book ourselves on how to downsize a teaching hospital."

Arnold also noted the governmental pressure to cut health care costs is producing some inequities in care and said that although Stanford is facing the issue of cost management squarely, "we aren't going to lose our ethical compass along the way."

Brunner said that up until recently, there really hasn't been any system of health care cost management. The system "has not been driven by normal economic factors," he said, and the providers have simply passed along charges to payers. Employers, as the payers, have felt it necessary to provide the necessities of life or were pressured into doing so. Employees have had the expectation of "totally unrestrained use of the health care system."

All three—providers, employers and employees—have been involved with bringing the system to the point it is, Brunner said, and all three must change their roles to reflect the new realities of cost management.

Fuhrman said there are "no quick fixes, no universal solution" to the problems of health care, but noted that the kind of approach being undertaken at the symposium was very encouraging.

"There are a number of places in the country where this kind of conversation would not be possible," he said. "A year ago, this kind of conversation wasn't likely even here in California."

At the end of the symposium, most of the participants indicated they woulc like to attend similar meetings in the future and Saga and Stanford officials were accepting suggestions for subjects that might be covered at future events.

EVEN LOW-INTENSITY EXERCISE IMPROVES AEROBIC FITNESS, STANFORD STUDY SHOWS

STANFORD—

Low-intensity exercise—a brisk walk, for example—is effective in improving the aerobic fitness of middle-aged, healthy, sedentary men, a Stanford University Medical School study has found.

This should be encouraging news for men in the 50-and-older age group, said Dr. Robert DeBusk, professor of cardiology. More than 90 percent who fall into this category do not exercise regularly because they're reluctant to embark on a strenuous exercise program. Their reasons include lack of time to participate in organized exercise programs and fear of injury or cardiovascular problems.

But now, they have no more excuses. In a study reported in the February issue of *American Journal of Cardiology*, DeBusk and his team found that after 12 weeks of low-intensity, home-based exercise, participants' aerobic fitness levels, measured by their peak oxygen consumption, improved eight percent.

Although they did not improve as much as their counterparts who exercised at high intensity for a 17 percent aerobic fitness improvement, the men far exceeded the control group of participants who did not exercise and did not benefit at all.

"We're directing this information not at younger active people but at a very large group of older inactive people who need to realize they can fit exercise into their daily schedules," DeBusk said.

A group of 64 healthy but sedentary middle-aged men participated in the study. Of the 64 men, 21 trained at a relatively low intensity of between 60 and 72 percent of the peak heart rates they had achieved during treadmill exercise testing. Another 23 men exercised at a relatively high intensity of between 75 and 87 percent of their peak heart rates. The remaining 20 men did not exercise during the course of the study.

The exercising men walked or jogged at home five times a week with no direct supervision for the duration of the study. Their exercise intensity was periodically measured by a computerized device, called a Vitalog, small enough to wear on a belt. The participants filled out daily reports about their physical activity, and received occasional phone calls of encouragement from the researchers. More than 90 percent of study participants kept up with their home-based exercise, proof that organized group programs are not the only way to ensure regular exercise and that home-based exercise is an viable alternative.

Results showed no differences in the resting heart rates of participants. But the aerobic fitness level of the men improved at a rate directly related to the intensity of their exercise.

The study "demonstrates that even relatively low intensity physical activity performed at home significantly augments functional capacity in normal sedentary middle-aged men," the researchers concluded. For many physicians who hesitate to promote exercise for older patients because of concern about the risks and discomfort, they added, low-intensity exercise provides an attractive option.

EDUCATION AND EXERCISE HELP STANFORD HOSPITAL HEART PATIENTS GET AN EARLY START ON RECOVERY

STANFORD—

On a Monday last November Albert Ingram was admitted to Stanford University Hospital's coronary care unit with a heart attack.

Within 72 hours, he was walking down the hall.

This week, only three months later, Ingram returns to work after racking up nearly a hundred miles of walking in the new exercise regimen that has given him a headstart on regaining good health.

Ingram was a participant in a cardiac rehabilitation program at Stanford University Hospital (SUH) that helps heart patients learn to take better care of themselves.

On Friday, Feb. 14, Valentine's Day, between 10 a.m. and 2 p.m., staff members involved in the program will sponsor an exhibit in the W1B waiting area of SUH to mark the second anniversary of the program's start.

In the two years since the program began, more than 500 patients with heart attacks, heart arrhythmias and other cardiac problems have participated with good results, says its coordinator, Denise Myers, R.N..

"A serious and sudden illness such as a heart attack can motivate people to change," explains Myers. "We try to capture that high level of motivation by teaching patients new health-promoting behaviors as early as their first day in the hospital."

Although the idea of encouraging heart patients to adopt better health habits is not new, promoting change from day one in the hospital seems particularly effective, Myers says.

"Positive reinforcement from nursing and medical staff, families and other patients, encourages patients to maintain behavioral changes even after they're discharged," she says.

Myers and two nurse colleagues, Barbara Ellis and Betty Linden, begin at the patient's bedside, where they help explain in everyday language what is wrong with the person's heart and what to expect from treatment.

The nurses use charts, diagrams, three-dimensional models of the heart, and a bedside slide show during the teaching sessions, in which they also provide information about medications, exercise, and diet. Spouses or others close to the patient are encouraged to participate.

The key to the program's effectiveness seems to be that it helps patients gain control of their lives at a very frightening time.

"Many people arrive on the unit terrified that they almost died," Myers explains. "They want to live, they are motivated, but they need the right information, resources, and plans to channel that high level of motivation."

While the patient is hospitalized, rehabilitation team members develop diet and exercise plans with the patient, and also help him learn proper medication schedules. They teach patients how to monitor their exercise levels and how to watch for new symptoms or for unexpected side effects of drugs.

Patients are referred to community services for continuing help. For example, those that want structured exercise programs or help in smoking cessation may join classes after they have left the hospital. For those who need special care or assistance at home, the nurses arrange for help through Stanford Hospital's home care program or other community services.

Patients go home feeling prepared to cope with a new lifestyle. "You have to reorganize your whole life after such a shock to your system," explains former patient Margaret Ayer. "Having the right information when I got home helped me very much."

Myers estimates that about 20 to 25 percent of the patients hospitalized in the coronary care unit and cardiac surveillance unit take part in the program. The patient's physician has to request participation, she notes. Dr. Charles Tucker, a cardiologist who practices at the Menlo Medical Clinic, uses the program frequently and calls it "excellent."

"The more patients understand what has happened to them, the more compliant they are in taking their medications and persisting in positive behavioral changes," Tucker explains.

Encouraging patients to be active partners in their own health care can help them overcome the natural tendency to feel defeated and depressed by their illness, Myers points out. Ivan Sindell, a program graduate, recalls that just three days after leaving intensive care he was doing warm-up exercises. "It was a real lift to the spirit," he says.

But the best effects are the ones that cause lasting change, adds Myers. "We help patients realize that they can actually be healthier after they leave the hospital than they were before they came," she says.

Dr. John Schroeder is the medical director of the program. Other members of the rehabilitation team include dietitian Lillian Tanabe, physical therapist Elizabeth Wright, occupational therapists Kerri Rohrkemper and Liz Bianchi, social worker Jane Zimmerman, discharge planner Liza Taft, and pharmacist Pete Jordan.

FOUR TO RECEIVE STANFORD HOSPITAL'S DISTINGUISHED SERVICE AWARDS

STANFORD—

Four individuals who have found widely different ways to help hospital patients have been named the 1985 winners of Stanford University Hospital's Distinguished Service Awards.

They are Maria Teresa Asquith, founder of the Mother's Milk Bank in San Jose; Diana Roth of Woodside, founder and chairman of Stanford Hospital's Patient Relations Associates program; Alice Green, who has opened her Palo Alto home to more than 200 out-of-town patients receiving care at Stanford; and Rabbi Sidney Akselrad of Congregation Beth Am in Los Altos, who helped create the hospital's chaplaincy service.

A committee of hospital administrators chaired by Jeanne Kennedy, director of community and patient relations, selected the award winners.

"We're proud to be a hospital that is supported by the community in so many different ways," Kennedy said.

The awards will be presented Feb. 18 in a ceremony sponsored by the hospital board of directors and administration. The presentation will take place at 5:30 p.m. in Fairchild Auditorium at the Stanford Medical Center.

This is the third time the awards have been presented. Previous winners were Kay Clair of the Assistance League of Santa Clara County, driving force behind the outpatient and family housing project now being constructed at 1100 Welch Road near the hospital; and Charles and Rose Jones, owners of Jones Mortuary in East Palo Alto, who have provided free burial service for many infants who died at the hospital.

Brief backgrounds on the 1985 winners:

Maria Teresa Asquith

In 1974, Maria Teresa Asquith was working as a technician for the Transplant Bank of the Institute for Medical Research in San Jose when the plight of a 7-month-old boy who needed mother's milk prompted calls for a milk bank in Santa Clara County. Asquith was asked to set it up, and after a visit to a milk bank operated by Children's Hospital in San Francisco, she did.

"I set it up and prayed," she said, explaining the prayer was for the $20,000 she knew was needed to get the project under way.

The March of Dimes and other community sources provided the money, and 12 years later, the Mother's Milk Bank is an undeniable success. It has supplied more than 400,000 ounces of milk for infants in hospitals throughout the Bay Area and Asquith has been invited to conferences on milk banks sponsored by the Surgeon General of the United States and the National Institutes of Health.

Financially, it's been a rougher road. Although the milk bank now gets some money from United Way as well as from fund-raising activities of the milk bank auxiliary and private donations, Asquith said that "year after year we were on the verge of closing."

But, she emphasized, "nobody was ever turned away because they didn't have the ability to pay" the usual milk processing fee.

There are only two full-time workers at the milk bank—Asquith and a technician. Another technician works part time, and everybody else is a volunteer. That includes 13 volunteer drivers and, of course, the more than 1,600 women who have donated their excess milk to help feed hospitalized infants.

Diana Roth

To Diana Roth, a patient relations associate is "as close to being a professional as you can be without being one."

Members of Stanford's associates undergo a professional training period and they often put in professional-type hours ministering to the needs of hospital patients. Some are on call 24 hours a day. "We've all been called at 2 or 3 in the morning to come over," Roth said.

She was a hospital auxiliary member when she got involved in founding the associates program in 1980 and she has seen the numbers grow to the present complement of 24 on active service.

The associates are actually patient advocates and do anything needed to help patients. That includes helping to clear up any misunderstandings between patients and medical staff, meeting arriving patients, providing lodging and transportation for patients and their families—and sometimes talking over with families crucial decisions on life support systems.

The hours can be long and the work hard, while the monetary rewards are nonexistent. But Diana Roth knows there are a lot of other rewards. "It's one of the most worth-while things I've ever done or will do," she said.

Alice Green

Recently widowed Alice Green was out of state visiting her daughter in the fall of 1977 when she got a telephone call from Stanford Hospital Chaplain Ernle Young. He said he had a young woman at the hospital who wanted to stay in a private home. Would Green take her in for a while?

She would, and did. Now, more than 200 house guests later, she has a home full of memories and the lasting affection of those she has helped.

It's like having a big, extended family, she said, calling a Brazilian medical student who came to Stanford Hospital for cancer treatment "my South American daughter."

Sometimes having an extended family means sharing extra grief. Green recalls the death of a patient whose wife and son were staying with her. "I was up and waiting for them when they came home," she said. "You just have to be able to give a lot of support, comfort and let them cry."

Most of the time, though, the visits to Green's home end happily and the patients return to their own homes. A lot of them keep in touch with Green, and often invite Green to visit their homes. She has accepted on a couple of occasions and is hoping to have the opportunity to accept the invitation to visit the Singapore home of a former patient.

Rabbi Sidney Akselrad

Rabbi Sidney Akselrad has been involved with the chaplaincy service at Stanford Hospital since before it was started in 1974, but he's been involved with the hospital for much longer.

"I've been coming here for 24 years," he said, explaining that when he was appointed to Congregation Beth Am he began visiting Stanford as a volunteer Jewish chaplain because of his experience in hospital visitation in Cincinnati and Detroit.

"No matter where I have served one of my emphases has been hospital visitation," he said. "When people are hospitalized it's one of the most sensitized times of their lives. It's also a time when they most appreciate a visit from a clergyperson."

With that background and his familiarity with Stanford Hospital, Akselrad was a natural choice for the committee of religious leaders that helped create the hospital chaplaincy. "With people of so many different faiths from so many different parts of the world coming to Stanford (for treatment), we felt it was necessary to serve their spiritual needs as well as the physical," he said.

Since the formation of the chaplaincy service in 1974, Akselrad has been a member of the Chaplaincy Advisory Committee and has been active in establishing the Jewish component of the chaplaincy program.

MEDICAL SCHOOL COURSE UNDERSCORES PERILS OF NUCLEAR ARMS RACE

STANFORD—

"Take a deep breath," Gary Lapid says.

The class watches in awe as the psychiatrist climbs up on a stool, pitcher in hand, and peers over the table with an empty copper container resting on top of it.

"I'll now demonstrate how 18,000 nuclear warheads may sound like when they explode in sequence," Lapid calmly explains. "The beans I have in this pitcher represent the combined nuclear arsenal of the United States and the Soviet Union. It's equal to the firepower of 6,000 World War IIs."

The students gaze at the psychiatrist, then at each other in suspenseful silence.

"I know this is going to be difficult for some of you," Lapid says softly. "I want you to close your eyes as I do this. Then find someone near you. Talk to each other about what you're about to experience."

Lapid takes a bean out of the pitcher. Holding it high above the container, he tells the class, "This represents all of the firepower of World War II--three megatons." He lets it go. The bean ends up at the bottom of the metal container with a resounding clang.

He reaches into the pitcher again. "These beans represent 9 megatons, the weapons of just one Poseidon submarine, enough firepower to destroy over 200 of the Soviets' largest cities," he says. "The Soviets have similar levels of destructive power."

Now Lapid empties the pitcher slowly into the container. Each clang is an imagined nuclear detonation, a giant fireball hotter than the sun, incinerating everything in its path, with devastating winds of more than 550 miles per hour. The process of emptying the pitcher of beans takes about a minute. If it happens in real life, if someone deliberately or accidentally pushes the wrong button, it's the destruction, the end of civilization, Lapid says.

Next, Lapid tells the visibly shaken students to be silent, to ponder what they have just heard and imagined.

Scary stuff? Yes. But it could happen say the physicians who organized this unique one-day course to underscore the perils of the nuclear arms race. "Exploring the physician's role in a nuclear age" was attended by 30 medical students and faculty Saturday in Fairchild Auditorium of the Stanford University School of Medicine.

The course was organized by psychiatrist David Daniels and his colleagues on the regular and voluntary faculty of the departments of medicine, psychiatry and surgery, and the local chapter of Physicians for Social Responsibility. The organizers included John Farquhar, Roland Finston, June Flora, Kate Forrest, Theodore Postol and Ward Trueblood, and two medical students, Stuart Shepherd and Jim Slayton.

Why should such a course be offered? Because with the massive stockpiles of nuclear weapons, serviced by tens of thousands of personnel and an estimated 10 to 20 additional nations obtaining nuclear bombs by 1990, said a handout distributed to the class, you can readily imagine a computer malfunction or human aberration upsetting the balance of a complex system and starting World War III.

Advanced technologies, which now allow one superpower to target another's nuclear missiles in a preemptive strike, have shifted the strategy from the mutual suicide pact that until now was the basis of deterrence to the possibility of fighting a nuclear war to win.

Studies of nuclear war scenarios in the range of 5,000 to 10,000 megaton yields have estimated there would be 750 million immediate deaths from the blast alone, 1.1 billion deaths from the combined effects of blast, fire and radiation and an additional 1.1 billion injuries requiring medical attention.

But Stanford radiology professor Herbert L. Abrams, a fellow at Stanford's Center for International Security and Arms Control, has concluded that a medical response in such a catastrophy would be inadequate. In his study, in which the United States is exposed to 6,559 megatons of nuclear explosives, Abrams wrote that the doctors, nurses and hospitals, because they are located in urban centers, will have perished also during the attack, to say nothing of disruptions in transportation and severe shortages in blood and medical supplies.

To create an understanding of this problem, Trueblood, a clinical assistant professor of surgery, showed slides from his experiences in Vietnam.

"We had the best transportation system and medical organization in the world," Trueblood said." But the nature of the injuries often required as many as six surgeons working on a single patient. Try to extrapolate that, to imagine what surgical and medical manpower will be needed to treat one million casualties."

Beyond the human casualties, said physicist Postol of Stanford's Center for International Security and Arms Control, will be the long-term biologicai effects on the ecosystems of the Northern Hemisphere, a condition scientists have labeled "nuclear winter."

Even though "nuclear winter" theories are fraught with uncertainties," Postol said, "we could be dealing with enormously catastrophic possibilities."

Smoke and dust will be injected into the atmosphere of much of the Northern Hemisphere, he said. The smoke effects may be more persistent than originally suspected. The smoke cover could linger for months, causing cooling of the ground and upper atmosphere, with adverse effects on agriculture and food supplies. The Soviet Union would suffer more from the cooling of the earth than the United States. This is because some believe the oceans might have a moderating effect on the North American continent.

The students were shown slides of how nuclear weapons look, the current and planned levels of U.S. and Soviet nuclear forces and early warning systems. They took part in exercises to learn how people of different ideologies and persuasions think, and how varying points of view can be redirected to constructive social change through communication.

They also learned that in 1983 figures, the United States military budget was $215 billion or $62 billion greater than it was in 1980, that the United States spends 6.7 percent of its Gross National Product for defense compared to the Soviet Union which spends 10.9 percent of its GNP, and that total defense spending by all countries is now close to a staggering $800 billion a year or $2 billion a day.

When thousands of children in third-world countries are dying from malnutrition, infection and disease, some countries are producing instruments of death, the speakers said. Physicians cannot remain apathetic to these developments.

Shepherd, a second-year medical student, said that increases in military expenditures have been accompanied by cuts in health programs in the United States.

A study by Victor Sidel of the Albert Einstein College of Medicine, distributed with the course materials, cites that in 1970 for an additional $120 million for six surveillance and command planes the Headstart program was cut by $20 million; for an additional $262.5 million for one submarine tender to support nuclear attack submarines, maternal and child health centers were cut by $112 million; for an additional $89 million for the Army XM 1 Tank program, mental health centers were cut $88 million. Similar cuts have affected cancer and other programs. Increases for armaments have continued for the past 15 years, Sidel concludes, at the expense of health programs. The cuts have added new burdens on state and local governments to provide these health services.

But the economic problems caused by the arms race have an impact beyond specific cuts on health services, Shepherd said. Economists have shown that support for human services depends largely on an expanding economy. Massive arms investments divert both capital and skilled people away from the modernization and productive capacity of a civilian economy.

"Japan," said Shepherd, "has spent far less than the United States for arms, and it has surpassed the world in its rate of economic growth and manufacturing productivity.

Citing economists, Shepherd added that military spending creates employment which does not contribute to increasing the supply of goods that consumers buy. It also eats up materials that would be used to produce consumer goods.

The problem, several speakers said, was "military addiction," which like all addictions is difficult to break. Many companies rely on military contracts for their survival, they said. When military expenditures are cut, they result in layoffs. They, in turn, create enormous pressures on Washington to restore military spending, leading to further stagnation in the nation's manufacturing capacity.

"But there are strategies for the nation's economic conversion from military spending," Shepherd said. "It can be done. True security must combine both defense and social and economic development."

Farquhar, director of Stanford's Center for Disease Prevention Research, said physicians have a responsibility to look at the root causes of problems and find ways to prevent them. "One can define international concerns about thermonuclear war as a new social movement," he said. "Physicians, because of their effectiveness as educators, can influence social change and behavior."

Interpersonal and mass media channels could be employed to effect changes in attitudes. "One example of a social movement that has succeeded is when 35 million Americans stopped smoking," Farquhar said. "It's a matter of influencing the way we think."

Farquhar noted that in 1985 some 37 articles on the effects of nuclear war had been published in scientific journals versus seven the year before. "That's amazing," he said, "since there are no government grants for this kind of work." Another positive development was the growth of the national membership of Physicians for Social Responsibility, from 1,500 in 1980 to 38,000 in 1985.

The result has been a shift in public opinion in the United States and in the Soviet Union regarding the nuclear arms race, the speakers agreed. This shift has had profound implications for nuclear disarmament.

VOLUNTEERS NEEDED FOR SEVERAL DIABETES STUDIES

STANFORD—

Several studies at Stanford University Medical Center are seeking volunteers to enhance researchers' understanding of diabetes and potential treatments.

One of the largest groups of studies regularly recruits about 250 persons annually, said Dr. Clarie Hollenbeck.

Hollenbeck coordinates volunteers for diabetes projects currently underway in the Clinical Research Center (CRC) at the Medical Center. Dr. Gerald Reaven, professor of medicine, directs the studies.

Hollenbeck said that the team currently needs persons, both with and without diabetes, for a study which is trying to determine if the fat cells of indviduals with diabetes respond differently to insulin than fat cells from individuals without the malady.

Diabetic and non-diabetic volunteers should be 20 to 75 years of age and in general good health. The diabetic volunteers may be on a controlled diet or taking oral agents but should not be taking insulin, Hollenbeck said.

The participants will spend two to three days in the resarch center during a two week period, and will receive at no charge to themselves a complete medical examination including blood chemistry and urinalysis, an EKG and dietary consultation.

In another study, researchers are testing a new oral medication and are seeking volunteers between 20 and 65 years who need treatment for their disease but are not currently taking insulin. The participants will spend three to five days in the hospital research center and then be monitored weekly for three months as they adjust to the new medication, Hollenbeck said. Participants will also receive general treatment for their diabetes as well as an extensive physical in return for their participation, she added.

A third study is seeking individuals between 35 and 65 years who are not responding optimally to large doses of insulin. The study, she said, will attempt to learn if supplementary oral medications will improve their response. This study also includes diabetes treatment and an extensive physical exam.

Persons interested in volunteering for a current study should contact Hollenbeck or Dr. Arthur Swislocki, a research physician, between 9 a.m. and 5 p.m. at (415) 497-6973.

Another research team is attempting to find the optimum diet for adult patients with diabetes.

Ann M. Coulston, research dietitian, said the current study consists of two six-week study periods during which all food and beverages will be provided for participants, who should be adults with diabetes not undergoing insulin injections.

Coulston said the volunteers will receive a complete physical examination, laboratory evaluation and nutrition counseling. The study is being held at the Clinical Research Center under Reaven's direction.

For further information on the diet study, contact Coulston between 9 a.m. and 4:30 p.m., at (415) 497-5430.

LEGISLATORS URGED TO REJECT RESEARCH INSPECTION POWERS FOR HUMANE SOCIETY OFFICERS

STANFORD—

Almost 50 faculty members of the Stanford University School of Medicine have written state legislators urging them to vote "no" on Senate Bill 1405, which would give humane officers authority to oversee research facilities' compliance with laws governing the use of animals in research.

The bill, by Senate President Pro Tem David Roberti, D-Los Angeles, has passed the Senate. It is expected to be taken up by the Assembly Judiciary Committee this month, and if approved by the committee will go directly to the floor of the Assembly. The Assembly bill differs somewhat from that approved by the Senate, but if it passes the Assembly it is considered certain to go to Gov. George Deukmejian with its main provisions unchanged.

Those provisions would expand the law enforcement powers of private citizens appointed by California humane societies. In the views of the Stanford physicians and many other researchers throughout the state, the bill could cause severe damage to biomedical research in California.

David Korn, vice president and dean of the medical school, summed up many of the objections in a letter he wrote to Assemblyman Elihu Harris, chairman of the judiciary committee.

SB 1405 would, he wrote, "Introduce humane officers to the conduct of biomedical research—a role most inappropriate and potentially dangerous. . . This bill in effect empowers a group of individuals philosophically opposed to biomedical research using animals to disrupt research and to make judgments on proper use of anesthetics, analgesics and other matters requiring substantial technical expertise."

That argument echoes part of a statement opposing SB 1405 endorsed by 19 members of the Coalition for Biomedical Research, including Stanford, the American Heart Association and the American Cancer Society. The coalition summarized its stand by stating, "Authority over life-saving medical research ought not to be granted to private groups which may be partisans in a highly emotional controversy."

The coalition also noted that existing laws provide for close monitoring of the use of animals in research. "The irony of considering SB 1405 now," the coalition stated, "is that never in history has more attention been focused on the proper treatment of animals in research or on ways of involving the public in the process of overseeing such research."

Other statements by Stanford physicians included:

2-6-86

-more-

Dr. Samuel Strober, professor of medicine and chief of the division of immunology: "The use of untrained personnel to monitor the research is as absurd as having untrained personnel participate in the research."

Dr. Norman Shumway, professor and chairman of the department of cardiovascular surgery: "Open heart surgery could never have evolved without animal research. Transplantation of the heart, which originated at Stanford, was born of animal research. . . All of the work that is in preparation today to make transplantation safer has its origins in animal research."

Dr. Stanley Falkow, professor and chairman of the department of medical microbiology: "I would assert as a working scientist that we are probably more concerned than most other members of the community that laboratory animals be cared for properly, kept in excellent health and as free from stress and pain as possible. . . The practical reality is, for improved health, animals are required for many kinds of biomedical research including those diseases which are very much in the mind of the public and legislators like AIDS, cardiovascular disease and cancer."

Dr. Roland D. Ciaranello, professor of psychiatry and chief of the division of child psychiatry: "The potential for mischief by uninformed groups is awesome. . . SB 1405 is a draconian departure from responsibility. It would effectively shut down all biomedical research using live animals, depriving the citizens of the United States of the innumerable benefits such work would have."

Dr. Avram Goldstein, professor of pharmacology: "If we are to learn more about why people become addicted to drugs, we have to study the addiction process either in people or in animals—there are no alternatives."

Dr. Lars M. Vistnes, professor of surgery and head of the division of plastic and reconstructive surgery: "It is my feeling that current laws and regulations under which an animal research facility, such as ours at Stanford operates, protect the research animals in a very admirable fashion."

Among the others who sent letters to the legislators were Thomas E. Hamm Jr., director of the division of laboratory animal medicine; Howard Schulman, associate professor of pharmacology; Dr. Frank E. Stockdale, professor of medicine in the division of oncology; Robert E. Kates, associate professor of medicine in the cardiology division; Carla J. Shatz, associate professor of neurobiology; Dr. Merton Bernfield, Josephine Knotts Knowles professor of human biology; Dr. Leslie J. Dorfman, associate professor in the department of neurology; and Dr. F. Blair Simmons, professor of surgery in the division of otolaryngology/head and neck surgery.

STANFORD PHYSICIAN GOES TO GLASGOW AS VISITING PROFESSOR

STANFORD—

Dr. Joseph Kriss, professor of medicine and radiology at Stanford University Medical School, will spend six weeks in Ireland as the Mcfarlane Professor at University of Glasgow.

He will also be admitted to the Honorary Fellowship of the College of Physicians and Surgeons of Glasgow "in recognition of the help given to Glasgow medicine by accepting people for training and also in recognition of a very distinguished career in academic medicine."

Kriss, director of the division of nuclear medicine, is renowned for his heart research and for his diagnosis and treatment of thyroid diseases. He has authored papers on a wide spectrum of nuclear medicine topics, including bone marrow scanning, hematological studies, renal evaluation, Gallium scanning for tumors, pulmonary scanning and nuclear cardiology.

The University of Glasgow's Mcfarlane Chair was established in 1962 by a private benefactor. During Kriss's stay there, scheduled from April 14-May 23, he will visit hospitals associated with the university and present teaching seminars and public lectures.

SUCCESS OF HOSPITAL FUND-RAISING CAMPAIGN LEADS TO SECOND PHASE

STANFORD—

Bay Area corporations have committed more than $1.4 million to Stanford University Hospital's modernization project (HMP) in a fund-raising campaign launched by a $250,000 challenge grant from Hewlett-Packard Co.

Hospital officials reported the "unprecedented" success of the campaign as they announced a second round of corporate fund raising aimed at bringing the total contributions from area companies to the $2 million level.

Dean Morton, executive vice president and chief operating officer of Hewlett-Packard and a member of the hospital's board, will head the second phase of the corporate fund-raising campaign. "The success of the initial phase really lays the groundwork for success in phase two," he said.

The campaign started last January with the announcement from H-P President John Young that his company would contribute $1 for every $4 raised from other corporations, up to a $250,000 maximum, to help finance the $114 million HMP.

Thirty-three companies responded, easily surpassing the $1 million needed to meet the H-P challenge.

Paul Edwards, the hospital's director of development, called the response "an unprecedented outpouring of corporate support for a Bay Area hospital, particularly with the two qualifiers that it was unrestricted giving by corporations and unrestricted giving for bricks and mortar."

Many corporations, Edwards noted, avoid making cash contributions to building projects and are more inclined to make gifts of needed equipment. He cited Hewlett-Packard and Apple Computer as examples of companies that usually give equipment but contributed cash to the HMP.

Apple was one of the companies that committed between $50,000 and $100,000 to meet the H-P challenge. Other major contributors included IBM Corporation, Pacific Bell/Pacific Telesis, PG&E, Saga Corporation, Syntex Corporation, Varian Associates, Advanced Micro Devices, American Building Maintenance, AT&T, Sunset Publishing and Wells Fargo Bank. Other local contributors included the real estate company of Hare, Brewer & Kelley, Crocker Bank and Lucky Stores, Inc.

Richard G. Rogers, recently retired president and chief operating officer of Syntex who headed the fund-raising drive, said he was "delighted with the result of the campaign. It shows the corporate community in Santa Clara County really is motivated to play a significant role in helping to make the cost of health care more efficient in our county by supporting an outstanding medical facility such as Stanford."

It also indicates, he said, "that the corporate community really does care about giving something back to the community from which it gets all of its people resources."

2-5-86

-more-

Edwards made the same point about the corporate sense of responsibility, noting that even though the fund-raising campaign began in the midst of an economic downturn "there were companies that came forward and came forward in an important way for a very important regional resource." He pointed out that contributions came "from as far south as IBM, in southern San Jose, and as far north as the banks in San Francisco."

To Morton, that corporate support goes beyond simple financial backing.

"It's important in terms of longer term relationships," he said. "When people give to and support a place like Stanford Hospital, it changes their attitude about it. They take a greater interest in it. I think over the long run that will probably have value beyond the $2 million or so that we raise."

The ongoing relationship between the hospital and the corporate community, Edwards said, is exemplified by a symposium on health care cost management that will be co-hosted by Saga Corporation and the hospital on Feb. 13. The symposium, to be held at Saga, will analyze health care costs from the corporate viewpoint and will include addresses by hospital officials. Officers of corporations throughout the Bay Area are expected to attend.

Besides getting help from the success of the first part of the fund-raising drive, Morton expects the second phase to benefit from the fact that "the hospital itself is well along in terms of construction."

"It's obvious that it's going to be an important modern facility," he said. "My guess is that our success in phase two will be facilitated by what happened in phase one and by the physical evidence of the project going forward."

The modernization project is scheduled for completion in 1987. It will provide 20 new operating rooms, modern intensive care units, consolidation of many clinical laboratories now scattered throughout the hospital and medical center, new isolation and recovery rooms, anesthesia space, facilities for magnetic resonance imaging and a surgicenter for outpatient procedures.

NEW TEST DETECTS POTENTIAL CANCER-CAUSING AGENTS WITHOUT USING LABORATORY ANIMALS

STANFORD—

A new, more precise method for identifying potential cancer-causing chemicals has been developed by Stanford University School of Medicine researchers.

The method examines substances' harmful effects directly in human cells, making it more accurate than the Ames test, which screens potential cancer-causing compounds in bacteria.

The process can be carried out in laboratory "test tubes" without the need to expose animals to chemicals, another standard procedure for detecting hazardous substances, according to its developers.

The test pinpoints mutations, slight chemical changes in DNA, the cell's genetic master molecule. Mutations alter the genetic message, sometimes causing minor aberrations in cell function, in other cases leading to cancer. One leading model of cancer formation proposes that mutations in certain human genes transform them into cancer-causing genes, or oncogenes.

Although the new test requires further development and study before its powers are fully evaluated, it is expected to be of interest to the pharmaceutical, pesticide, and other chemical industries that are required to document the dangers of chemical compounds they produce.

The test also may be a valuable basic research tool that could lead scientists to a more precise molecular understanding of mutation and of certain rare genetic diseases that predispose their victims to cancer.

The research was conducted in the laboratory of Dr. Michele Calos, assistant professor of genetics at Stanford University School of Medicine.

An article describing an early version of the test method was published in the December issue of the *Proceedings of the National Academy of Sciences*.

Calos' co-authors on the article are Dr. Jane Lebkowski, a former Stanford postdoctoral researcher, Suzanne Clancy, a graduate student, and Dr. Jeffrey H. Miller of the University of California in Los Angeles. Others involved in the work are Bob DuBridge, a graduate student, Michele Schwartz, a medical student, and Peter Tang, a research assistant.

Since that article was written, Calos and her group have refined the test system to be faster and more sensitive. The refined test also permits chemicals to be screened in cells from different kinds of human tissues. Research by Bill Sugden at the University of Wisconsin played a vital role in the new refinements, Calos said.

"What we're really trying to do is model the human organism in tissue culture because we obviously won't do these kinds of experiments directly on people," Calos explained.

The advantage of being able to use different cell varieties is that it could shed light on how and why different types of cancer arise. "Different tissues may be more susceptible to mutations caused by certain chemicals," Calos pointed out.

2-5-86

-more-

These kinds of tissue differences can't be explored using the Ames test, which for many years has been the gold standard in screening for mutagens, substances that cause mutations, Calos explained.

Some potentially dangerous or harmless chemicals can be misread by the Ames test, she added. "Our bodies have some enzymes which bacteria lack, that activate otherwise harmless chemicals into mutagenic compounds, and inactivate others" she explained.

The test can also measure effects of other mutagenic agents such as ultraviolet light, on human cells, and it could be useful for studying chemicals that are touted to prevent cancer, Calos said.

"You've probably already heard claims that vitamin C can prevent cancer and seen ads on television for beta-carotene to ward off cancer," she said. "But no one has compelling proof that these compounds really work."

The method would enable scientists to test those claims, she suggested, by actually measuring whether or not they can decrease the mutation frequency in human cells.

The key to the new method is that scientists use a transportable piece of DNA as the mutation target. This piece of DNA is a bacterial gene whose structure down to the last atom is already known.

They slip the gene into a human cell and then expose the cell to the chemical or other agent being tested.

Later, they remove the target gene and return it to bacteria where the number and nature of the resulting mutations can be easily detected and analyzed.

The research was supported by grants from the National Cancer Institute, the National Institutes of Health, the Chicago Community Trust/Searle Scholars Program, and the Leukemia Society of America.

STANFORD TO HOST FEB. 14 CONFERENCE ON ALCOHOLISM

STANFORD—

"Improving the Effectiveness of Alcohol and Drug Treatment" will be the focus of the second annual Stanford Conference on Alcoholism on February 14 at the Hyatt Rickeys in Palo Alto.

During the day-long conference, seven guest faculty will discuss research in areas intended to help treatment providers improve care given to alcoholics and their families. Problems with alcohol affect an estimated 70 million people nationwide.

About 150 physicians, nurses, family therapists, alcohol and drug counselors, social workers, psychologists and others who work with alcoholics are expected to attend the conference.

In the past, alcohol programs were gauged to be anywhere from highly successful to barely helpful—but measurement methods varied so widely that trying to examine programs "was like comparing apples and oranges," contends Dr. Robert Matano, conference co-chairman with Dr. William Hazle.

Now, however, more uniform ways of evaluating programs have been developed. This information allows treatment to be tailored to individuals, boosting success rates, according to Drs. Hazle and Matano, who are Stanford researchers.

"Improving the Effectiveness of Alcohol and Drug Treatment" is co-sponsored by Stanford University's Department of Psychiatry and the Stanford Alcohol Clinic.

Drs. Hazle and Matano direct Stanford's new Alcohol and Drug Treatment program, which offers highly flexible, individualized care. Dr. Hazle, a psychiatrist, serves as medical director of the program; Dr. Matano, a psychologist, is program director.

Continuing medical education credit is offered for the course, which costs $65. There is no charge to members of the press. For more information or registration information, call Diana Kennedy, 497-6682.

JOURNALISTS, SCIENTISTS TO DEBATE HUMAN GENE THERAPY, FEB. 13

STANFORD—

A day-long news media roundtable on human gene therapy, its ethics and national policy implications will be held February 13 at Stanford University School of Medicine.

The roundtable, the first of its kind on the West Coast, is designed to familiarize journalists with the topic of gene therapy trials in humans as they are getting closer to reality. The first guidelines for some forms of gene therapy were issued last year by the National Institutes of Health.

The program, which is open to the public, will begin at 10 a.m. in Fairchild Auditorium, with opening comments by Paul Berg, a Nobel laureate and director of Stanford's new Center for Molecular and Genetic Medicine. More than 300 journalists, faculty and students are expected to attend.

A panel of scientists will address the research issues in the morning. Besides Berg, it includes W. French Anderson, National Heart, Lung and Blood Institute of the National Institutes of Health; David Cox, University of California, San Francisco; and Theodore Friedmann, University of California, San Diego.

Laurie Garrett, science reporter for National Public Radio, will be the moderator.

Two panels starting at 2:30 p.m. will discuss gene therapy--ethics and policy. It includes Robert Cook-Deegan, Office of Technology Assessment, U.S. Congress; Eric Jungst, ethicist, University of California, San Francisco; Marc Lappe, author of *The Broken Code: the Impact of the Recombinant DNA Revolution*, University of Illinois; and Nancy Wexler, Hereditary Disease Foundation.

A panel of journalists will question the participants. The journalists are Yvonne Baskin, freelance writer and author of *The Gene Doctors*; Linda Herskowitz, medical writer, *Philadelphia Inquirer* and Knight Fellow, Stanford; and David Perlman, science editor, *San Francisco Chronicle*.

Pulitzer prize winning journalist James Risser, professor and director of the Knight Fellows Program, will moderate the afternoon session.

Presently, the key targets for gene transfer are maladies in which scientists hope to introduce a needed gene product into the appropriate tissue. Eventually some 3,000 diseases known to be caused by one or another single defective gene could be amenable to gene therapy, scientists believe.

But transplanting good copies of a gene into a patient's cells requires more research of how genes are organized, their regulation and other aspects now very poorly understood.

Scientists only plan to transplant genes that do not lead to inherited changes. But some people fear someone may someday attempt to redesign the human race by tranplanting genes into sex cells that lead to inherited changes. Even though the technical feasibility to do this does not presently exist and no one has proposed such studies in humans, this factor has fueled a continuing debate over the ethics of gene therapy.

The Media Outreach Program is a cooperative project of the American Association for the Advancement of Science, the Association of American Universities, and the Scientists Institute for Public Information. It is funded by a grant from the Andrew W. Mellon Foundation.

Stanford hosts are the Departments of Communication, and Family, Community and Preventive Medicine.

Coordination is provided by the Medical Center's Office of Public Events and Office of Communications.

STANFORD HOSPITAL PATIENTS GET FREE USE OF TV

STANFORD—

Stanford University Hospital has made television use free to all patients and has signed a new contract designed to substantially improve television service.

The actions were taken after three surveys showed television cost and maintenance were two areas that produced a high number of patient complaints.

Patients, physicians and nurses were all interviewed for the surveys, which were conducted over the past year by a 16-member patient television committee chaired by Jeanne Kennedy, director of community and patient relations.

The hospital contracted with J. Allen Corp. of Burlingame to provide new television sets and pillow speakers. The company also will provide three hours of service daily for the television operation.

Television service formerly cost $3.50 a day. Donna Pronko, the hospital's patient relations coordinator, said that most hospitals on the Peninsula continue to charge for television use, although some in the East Bay offer free television.

She said the hospital plans to expand its closed-circuit programming and will supply a wider range of educational and entertainment programs on channel 3 and channel 17.

EXERCISE INCREASES THE ACTION OF INSULIN IN METABOLIZING SUGAR, STANFORD STUDY SHOWS

STANFORD—

A new Stanford Medical Center study shows that regular exercise helps the body metabolize sugar more efficiently by increasing the body's sensitivity to insulin.

People who exercise regularly -versus those who don't- secrete less insulin "to accomplish the same task," said Dr. Gerald Reaven, Stanford professor of medicine and endocrinologist.

This study has implications for the treatment and understanding of type II diabetes, a disease caused by resistance to the action of insulin.

Insulin is a hormone that stimulates glucose (sugar) metabolism and stabilizes the amount of sugar in the blood.

The study supplies substantial evidence for understanding what many scientists already believed through inference: that exercise plays a key role in determining how well insulin works, Reaven explained. This study also provides a clue to the basic mechanism of this phenomenon.

The study was presented at a Feb. 6 subspecialty meeting held after the annual Western Association of Physicians meeting in Carmel, CA.

Normally, cells in the pancreas make insulin and secrete it into the blood after meals. This stimulates other body cells to take up glucose from the blood. Once inside, glucose can be used as fuel for the cells.

By secreting specific amounts of insulin at appropriate times, the body is able to maintain a fairly steady blood-glucose level, Reaven said. "An hour after a meal you are right back where you started from, and perturbations in the blood-sugar level are very small," he said.

"A diabetic is someone whose blood-sugar level is always too high," Reaven said. This, in conjuction with other factors, may result in blindness, heart attacks, kidney failure, gangrene and damage to nerves and blood vessels.

Type I diabetes is caused by a failure to secrete insulin at all. These diabetics require regular injections of insulin to make up for their deficiency. Type II diabetics secrete plenty of insulin; some secrete up to twice the normal amount, Reaven said. But, despite their ability to secrete insulin they are diabetic, leading doctors to believe that they are resistant to the action of insulin.

For these people, an exercise program to increase insulin sensitivity "ought to be useful therapeutically," Reaven said.

But pragmatically, "If you have a 68-year-old diabetic who is 42 pounds overweight and has never exercised in her entire life, the chances of making substantial in-roads in that person are not too great," he said.

Also, "no one really knows yet how much exercise training you have to have to make a real impact, but it is not insubstantial," he said.

This study compared active runners to people not in active training, but "who were just as healthy and were matched for other variables,' Reaven said.

-more-

Previous studies by Reaven and his team have shown that in normal people "there are great differences in insulin action." Approximately 50 percent of this variability is accounted for by degrees of obesity and physical fitness (which often go hand in hand), Reaven said. "The other half is unknown; it could be genetic, it could not be," he said.

Understanding the relation between exercise and insulin sensitivity helps explain why being obese appears to increase an individual's chances of developing diabetes. Nearly two-thirds of all type II diabetics are overweight.

Basically, if a person has a high resistance to insulin, getting heavier and more sedentary makes the problem worse, Reaven said. "The fatter and the lazier you get, the more likely you will get the clinical syndrome" of diabetes, he said.

However, if the problem is bad enough, a person will get the disease whether they are overweight or slim. "That is why there are many non-fat diabetics," Reaven said.

But, "there is no question that (getting heavy and sedentary) is a risk factor" in developing type II diabetes.

Understanding the relationship between exercise and insulin sensitivity may also explain why people become more insulin resistant as they age, Reaven said.

"As people get older, they often get more sedentary and heavier." But in reality, "if you are active when you are older, your glucose metabolism seems to be very normal," he explained.

At the sub-cellular level, Reaven's study isolated where the basic mechanism for the effect of exercise on insulin sensitivity takes place. When insulin is released into the blood stream it binds to receptor molecules, which is necessary for the cells to take up glucose, he said.

By comparing insulin binding and glucose uptake in cells from exercised trained and untrained individuals, scientists isolated the effect of exercise to be after insulin binds the receptor, Reaven said.

He said the participation of volunteers made this study possible, and his research team is currently seeking additional diabetic and non-diabetic volunteers between the ages of 20 and 75 to participate in other studies. In exchange for their participation, volunteers receive a free comprehensive medical and physical examination, general treatment for their diabetes, and the opportunity to participate in on-going research.

Persons interested in volunteering for a current study should contact Dr. Clarie Hollenbeck, at (415) 723-0266 or Dr. Arthur Swislocki, at (415) 723-7024.

WOMEN AND HEALTH TO BE TOPIC OF STANFORD LECTURE SERIES

STANFORD—

Health issues and their impact on women will be explored in nine free lectures open to the the public at Stanford University Medical Center during April and May.

Health insurance, stress, childbirth and nutrition are some of the issues to be covered each week in the noontime, hour-long lectures.

The Women and Health Series has been held each year since 1977; this year, however, it has been named for its founder, Leona McGann, assistant professor emerita of family, community and preventive medicine. The McGann Women and Health Series is sponsored by the division of family medicine.

The lectures will be held at noon on Fridays in room M-112 of the Medical School.

Lecture topics and dates follow:

April 4: "Menstrual Myths and Reality: Psychosocial Research on Menstruation," Barbara Sommer, Ph.D., department of psychology at the University of California, Davis; and board member of the Society of Menstrual Cycle Research.

April 11: "The Wisdom of Our Bodies," Patricia Sun, philosopher of wholeness and international lecturer in communication and creative thinking.

April 18: "Black Women's Health Issues: Taking Care and Taking Charge," Felicia Ward, co-director, Bay Area Black Women's Health Project.

April 25: "Women Coping with Health Insurance in the 80s," Leona McGann, M.S.W, M.P.H., Stanford assistant professor emerita of Family, Community and Preventive Medicine, and Director of Stanford Health Insurance Training Project; and Shirley H. Wattenberg, associate professor of the School of Social Work and College of Medicine at the University of Illinois, Champaign-Urbana.

May 2: "Coping with Stress in the 80s," Anne Baldwin, R.N., Ph.D., nurse consultant to Stanford University Hospital.

May 9: "Mothers and Midwives: A History of Childbirth from Prehistory to the Present," Janet Ashford, author of the Whole Birth Catalog and editor of Childbirth Alternatives Quarterly.

May 16: "Delivering Good Care: The Oakland Midwives' Struggle," Debbie Le Veen, Ph.D., associate professor of urban studies and public administration at San Francisco State and a member of the California State Alternative Birthing Methods Study Advisory Committee.

May 23: "Update on Women's Nutrition Issues," Debbie Waterhouse, M.P.H., R.D., nutrition consultant to the Wellness Program at Merritt Perolta Institute.

May 30: "Alternative Childbirth and the Malpractice Insurance Crisis," Rosemary J. Mann, C.N.M., J.D. and director of the Women's Health Care Training Project at Stanford.

NEWS CONFERENCE ADVISORY

STANFORD—

Stanford Medical Center has scheduled a news conference at 10 a.m. Wednesday April 2 to announce participation in a $15 million initiative by the Henry J. Kaiser Family Foundation, Menlo Park, to develop health promotion projects in communities across the nation, beginning with 13 Western states.

Speaking at Stanford will be Dr. John W. Farquhar, director of the Stanford Center for Research in Disease Prevention (SCRDP) and professor of medicine, and Dr. Robert Melton, director Monterey County Health Department, where an active SCRDP intervention program has been in progress for about 10 years. Foundation officials will also be available.

The Kaiser grant, which will be announced simultaneously in Washington, D.C. designates the Stanford Center for Research in Disease Prevention (SCRDP) as the first of several Health Promotion Resource Centers which under the foundation's auspices will aid communities in developing community health projects. A pioneer in community health education, Stanford has a 15-year history of developing community-based health education efforts. A largescale project intended to change health habits on a community-wide basis currently is continuing in Monterey County.

The Foundation's proposal, intended for the first time to expand the principles developed at Stanford and other centers to eventual nationwide availability, will be unveiled in Washington, D.C. at the same time as the Stanford conference. The Washington briefing will be telecast live at 10:15 a.m. via a satellite hookup to persons attending the Stanford news conference. The Washington announcement will be made at a briefing for representatives of medical, labor, civic, educational and other organizations that will be involved in the projects, plus Congressional representatives, federal officials and journalists.

The Stanford news conference will be held in Room TE 110, the conference room in the Psychiatry Building. The room is located on the extreme Western (mountain) side of the Medical Center in a two-story redwood temporary building near Sherman Fairchild Auditorium. Limited parking will be available for newsmen in the parking lot adjacent to the building.

Remote feeds are to be available to media personnel for recording.

MEDICAL STAFF KEY TO SAVING LIVES, HOSPITAL STUDY SHOWS

STANFORD—

The quality of physicians and nurses is more important than advanced technology in saving the lives of severely ill patients, according to a study of intensive care units in 13 major U.S. hospitals.

Stanford University Hospital was one of the institutions surveyed in the study, which was directed by Dr. William A. Knaus of George Washington University Medical Center in Washington, D.C., and reported in the March issue of *The Annals of Internal Medicine*.

The study made a statistical comparison of the death rates of 5,030 ICU patients at the 13 hospitals, but the report did not identify the ranking of the hospitals. Knaus said identification of the ranking was prohibited by the terms of the study grants from the National Center for Health Services Research and the Robert Wood Johnson Foundation.

The report said that 11 of the hospitals were grouped in a broad middle range with death rates about as expected. One hospital, however, was significantly better than all the others and one hospital was significantly worse.

Hospital number 1, the report said, emphasized reliance "on carefully designed clinical protocols implemented by senior level in-unit physicians. This hospital also had the most comprehensive nursing educational support system. . . As a result of this educational program, the nursing staff at Hospital 1 had independent responsibilities within the clinical protocols. Excellent communication between physicians and nursing staff was ongoing to ensure that all patient care needs were met.

By contrast, hospital number 13 "lacked a comprehensive nursing organization" and "admitting physicians and unit nursing staff coordinated poorly. In fact, the study said, "frequent disagreements about the ability of the nursing staff to treat additional patients occurred, and there was an atmosphere of distrust."

Those two approaches produced marked differences in the ratio of actual deaths to those predicted according to certain risk factors. While the ratio for most of the hospitals was close to 1—in other words, the number of deaths about as expected—the ratio for the top hospital was .59 and that for the last-place hospital was 1.58. That means the top hospital had a death rate 41 percent lower than predicted and the last hospital had 58 percent more deaths than predicted.

-more-

3-28-86

In concrete figures, there were 41 deaths at the first-place hospital in comparison with 69 that were predicted, while the last-place hospital had 52 deaths compared with a prediction of 33.

A system called APACHE II (Acute Physiology and Chronic Health Evaluation) was used to prepare the death estimates. In that system, weights were assigned to 12 physiologic measurements taken during the first 24 hours of ICU treatment. Those values were combined with other values such as the patient's age to obtain the death prediction.

The report emphasized that statistics were examined in several different ways to reduce the possibility of misleading conclusions. "We could find no measurement biases that would have systematically favored one hospital over another," it said. "Therefore, we are confident that the results represent real differences in therapeutic efficacy that are related to differences in the process of care and, specifically, in the interaction and coordination of the unit staff."

There were 10 teaching hospitals and three nonteaching hospitals in the study. Although the top-rated hospital was a teaching hospital, the next two were nonteaching, a somewhat surprising result because hospitals affiliated with medical schools usually care for the most severely ill patients and are considered to have higher comparative survival rates.

Those results, according to the report, indicate that "intensive care units do not have uniform results among large teaching hospitals. Large tertiary care teaching hospitals, although generally treating a greater number of severely ill patients and doing more complex operations, may not achieve optimal results based solely on teaching status. These hospitals must develop highly coordinated systems for management of their patients, similar to the one used in Hospital 1."

In addition to Stanford, the teaching hospitals in the study were Cooper Medical Center, Camden, N.J.; Johns Hopkins Hospital, Baltimore; Maine Medical Center, Portland; Massachusetts General Hospital, Boston; Medical College of Georgia, Augusta; University of Maryland Hospital, Baltimore; University of Virginia Medical Center, Charlottesville; and University of Wisconsin Hospital and Clinics, Madison.

The nonteaching hospitals were Polyclinic Medical Center, Harrisburg, Pa.; St. Francis Hospital, Tulsa, Okla.; and South Shore Hospital, Weymouth, Mass.

STANFORD CONSIDERS JOINT VENTURE FOR PSYCHIATRIC CENTER

STANFORD—

Stanford University is considering affiliating with a major for-profit health corporation in an arrangement that would provide a new psychiatric building near the Medical Center.

If a satisfactory agreement can be worked out, it would produce a full-fledged psychiatric center at Stanford without touching the strained capital budgets of the University or the Hospital.

Construction of the building would be financed by the corporation and operation would be a joint venture. The building would allow consolidation of widely dispersed academic functions and clinical programs of the Department of Psychiatry and Behavioral Sciences.

The executive committee of the School of Medicine approved preliminary negotiations with health corporations at its meeting Friday, March 21, after Dean David Korn presented the report of a task force recommending such negotiations. The concept previously was approved by the Hospital Board of Directors and the University Board of Trustees' Committee on the Medical Center.

Sheldon King, Hospital president and chief executive officer who chaired the task force, said the new facility would cost between $15 million and $25 million and probably would have 60 to 80 beds.

Both King and Korn emphasized that if negotiations produce an agreement, Hospital and University interests would be protected in any contract. "We'll be extremely careful and proceed with caution," Korn said.

Korn called the proposal "a precedent-setting effort to undertake this pathway of capital acquisition," and King said it was "a way of having an arrangement (we want) while safeguarding University and Hospital funds."

Although such an arrangement would be new to Stanford, there have been a number of similar affiliations between hospitals and for-profit corporations. King noted that Vanderbilt University and the Hospital Corporation of America (HCA) are working together on a similar psychiatric facility.

Other examples of successful alliances include American Medical International (AMI) with Creighton University in ownership and operation of St. Joseph's Hospital in Omaha and National Medical Enterprises (NME) with the University of Utah in ownership and operation of a new psychiatric hospital.

In addition, McLean Hospital, one of Harvard Medical School's leading psychiatric institutions, has just signed an agreement with AMI to do business through a newly created company called McLean Medical Services, Inc.

The Stanford task force recommended that a non-profit form of operation would be best for the psychiatric facility but noted that any corporation agreeing to finance construction of a new building would expect a return on its capital investment.

3/27/86 more

King said a corporation might be willing to accept a small return because of the desire to have a "flagship" operation associated with Stanford.

The building would be on Stanford land, which the University would lease to the corporation.

In summarizing the need for a new building, the task force said, "Stanford's Department of Psychiatry and Behavioral Sciences is well established and preeminent in many areas of the discipline, despite its relatively small faculty and its limited and limiting facilities.

"To continue this tradition of excellence the department must expand its clinical activities and, at some future time, its faculty. Neither is possible given current facilities. Further, the department's strong interdisciplinary tradition and commitment to an accessible teaching environment are hampered by the geographic dispersion of facilities."

As examples of that "geographic dispersion," the report pointed out that the department has clinical programs in such widely scattered locations as the Medical Center, the Palo Alto Veterans Administration Medical Center (VAMC), Children's Hospital at Stanford, San Jose Hospital, Cowell Student Health Center and Santa Clara Kaiser Permanente Hospital.

All of those sites have deficiencies in addition to their locations, the report noted. VAMC, for example, has a patient population "confined almost exclusively to men of a certain socioeconomic stratum," which limits opportunities for research and teaching.

Teaching, research and administrative space for the department is also widely scattered, the task force said, which "hampers collaboration among faculty members, and, more importantly, impairs students' and trainees' exposure to the rich intellectual milieu of the faculty as a whole."

STUDY SUGGESTS A NEW DRUG CAN TEMPORARILY CONTROL VIRAL INFECTION COMMON IN AIDS

STANFORD—

A common viral infection that often turns fatal in patients with immune deficiencies—including acquired immune deficiency syndrome (AIDS)—can be temporarily controlled in certain patients with an experimental drug, a new study has found.

The drug, known as DHPG, was able to temporarily improve the conditions of 17 of 22 patients with underlying immune deficiencies who had contracted cytomegalovirus (CMV) infection, according to the study published in the March 27 issue of *The New England Journal of Medicine*.

But despite the initial improvement, most of the patients subsequently had a relapse of the viral disease and a majority of the patients died within 10 months after completing treatment.

The researchers, however, are encouraged that the drug offers promise as a treatment for CMV, an infection that is currently untreatable and can produce fatal complications in AIDS, and other, patients.

"This is certainly not a cure for AIDS and not even a cure for CMV. But it is a foot in the door in a situation where we really had no effective treatment approach before," said Dr. Thomas Merigan, Becker Professor of medicine at Stanford University School of Medicine and chairman of the collaborative study group.

"This study gives hope that a drug can be used to intervene in CMV infection," Merigan added, "but it has to be judged as only the beginning of this drug's study. We've got to improve on its action."

Merigan's colleagues included Dr. Stuart Koretz of Syntex Research in Palo Alto, who was study director, Drs. William Buhles, Austin Brewin, and Robert Roe, also of Syntex; Drs. Jack Bissett and Mark Eisenberg from Stanford, and researchers from 15 other collaborating medical institutions in this country and abroad.

The research was supported by a grant from Syntex Research, which manufactures the drug DHPG. The experimental drug, whose chemical name is 9-(1,3-Dihydroxy-2-propoxymethyl)guanine, is also manufactured by other pharmaceutical companies and is known by several other names.

CMV is a common virus that infects almost everyone at some time in life, and usually causes an infection so mild that it goes unnoticed, Merigan explained. But in people whose immune systems are weak or not working properly, CMV can become a serious, often fatal, disease involving the eyes, central nervous system, lungs, gastrointestinal tract, or liver.

Those at highest risk of a serious infection include organ transplant patients who are on immunosuppressive drugs, some patients with cancers involving cells of the immune system, newborn infants who contract the infection from their mothers, and AIDS patients, Merigan said.

In the study, 26 extremely sick patients thought to be dying from CMV infection were given DHPG on a "compassionate use" basis. "This is a way of making an experimental drug available, on a patient-by-patient basis, because the circumstances are so compelling that there is no other therapy and the drug could be life-saving," Merigan explained. The drug has not yet been generally approved for use by the Food and Drug Administration.

3-27-86

more

Twenty-two of the patients had AIDS, two had received bone marrow transplants, one had a congenital immunodeficiency disease, and one was receiving immunosuppressive drugs. Although all were thought to have CMV infection when they were given the drug the researchers subsequently determined that four of the patients probably did not have CMV.

Among the remaining 22, 17 patients showed some clinical improvement when given the drug and five patients died before completion of the 14-day treatment, with no apparent benefit from the experimental agent. Of the 14 patients who could be followed up after the DHPG treatment was discontinued, 11 had a relapse of the infection.

"The important thing is that we can reproducibly suppress CMV infection with this drug. It's the only way we've got right now to get this virus," Merigan said. "However, with a disease like AIDS, you have such profound immune suppression that the moment you stop treating with the drug, the infection recurs.

"Among the patients who were helped, as long as they kept getting the drug, the disease was held back. Therefore, we're looking for ways to give the drug safely for long periods of time, or to combine it with other treatment strategies to get enduring suppression of CMV," Merigan added.

The drug was most effective in improving CMV infections involving the eyes and gastrointestinal tract. It was less effective when CMV involved the lungs, the study showed.

Vision in nine of 13 patients (69 percent) with CMV retinitis improved during DHPG treatment. The retinal infection stabilized in two additional patients given the drug. Only seven of these 11 patients were followed up. Five had a relapse of the CMV retinitis within two to six weeks after the therapy was discontinued.

Among the patients who had CMV infection involving the gastrointestinal tract, five of eight (62 percent) showed improvements such as a decrease in pain and diarrhea. Four of those five had relapses two weeks to three-and-a-half months after the drug was discontinued, the researchers said.

Among the seven patients with CMV pneumonia, four (57 percent) died of respiratory failure before completing the 14 days of treatment. Of the three patients who survived, all died of pulmonary failure within a few weeks after the treatment course had ended.

None of the deaths was attributed to DHPG, although the researchers added that the death of an additional patient treated following the original 26, could have been partially due to a decrease in white blood cells, the most serious of the drug's potential side effects. Other side effects included nausea, headaches, muscle pains, hallucinations, phlebitis, and fluid accumulation.

"This is the first agent that reproducibly suppresses CMV infection," Merigan said. "But it's just a beginning rather than a final effort. For now, all we can do is suppress the infection, rather than eradicate it."

DESPITE MUSCULAR DYSTROPHY, STUDENT EARNS PH.D. IN GENETICS

STANFORD—

Jeff Dangl didn't let muscular dystrophy stop him from going to graduate school, although he admits it may have slowed him down a bit.

"I can't buzz around the lab at 90 miles an hour, which is what most graduate students do," he explains.

Dangl, 28, just earned his Ph.D. in genetics from Stanford University Medical School and will soon be jetting to Germany where a postdoctoral research position awaits him.

For some people, a chronic disease might seem to close off the future, but Dangl credits his muscular dystrophy with opening up new doors. "My disease helped me see things I would never have known were out there," he says.

Dangl has a rare form of muscular dystrophy which causes extensive muscle weakness in his face, shoulders, arms and legs. Unlike the most common form of muscular dystrophy, Duchenne's, which strikes early, worsens through the teen years and is usually fatal by the 20s, Dangl's form of the disease first appears at puberty, generally plateaus in the mid-20s, and doesn't curtail life expectancy.

Nevertheless, "it was a traumatic thing," he recalls of his initial diagnosis at age 12. "I was at the stage where I wanted to be a handsome football player and all of a sudden I was falling down all the time."

His family was hit with a triple blow on learning that his younger brother and sister also had the disease, inherited from their mother who had a case so mild she didn't realize the affliction.

But the young family rallied, Dangl recalls. "My parents have always been very supportive of us," he says. "What we've gone through has made us all stronger, and because of it we're very closely knit."

At first a doctor in his northern California hometown of Redding diagnosed the condition as Duchenne's muscular dystrophy. But even when they later realized his disease was the less severe form, adjusting to the reality wasn't easy. "Because it was such a rare disease, I spent a lot of time as a guinea pig," Dangl recalls.

As a teenager, he made the rounds of medical centers and clinics up and down the state. He underwent surgery in which plugs of his muscle tissue were removed for examination, and allowed himself to be pricked and punctured with electrified needles to measure muscle contractility. He and his brother also took high doses of cortisone in an attempt to curb the disease.

"It was my first exposure to medical research," Dangl observes.

3/27/86

-more-

The medical forays reached a climax on one particular week-and-a-half stay at a hospital for children d teenagers with severe back and burn injuries. "At that point my family and I saw clearly that things could have been worse," Dangl remembers. "I realized that my condition was nothing compared to what a lot of people have to go through. I'm constantly amazed when I see people who have severe handicaps. They deserve much respect."

Dangl's positive outlook helps him surmount the obstacles life throws in his way. In day-to-day activities, his disability forces him to be highly organized. "Getting up and down is difficult," he explains. He plans each move in advance, and tries to arrange his surroundings with conveniences such as bookshelves he can reach while seated at his desk.

Dangl says he has become highly sensitized to issues such as building access. "I can walk, but I have a real hard time with stairs and with gravity in general," he explains. "I much prefer walking up an access ramp to stepping up a curb."

While he was an undergraduate at Stanford, Dangl got around the sprawling campus in a golf cart provided to him through the Department of Rehabilitation, a state agency that provides assistance to people with disabilities of all kinds. The help he received through the agency's staff was critical, Dangl says, but he is now worried that others won't be able to obtain similar benefits because of state government budget-cutting pressures.

Another concern focuses on the young people in his hometown. Noting a recent rash of suicides among students at his former high school, Dangl reflects on the fact that kids growing up in a small town may have a harder time finding new opportunities. "Maybe I can be a role model, to let kids know that there are options," Dangl suggests.

Dangl's thesis research, in which he used genetic engineering techniques to study how the immune system's antibody molecules function, was conducted in the laboratories of Stanford genetics professor Dr. Leonard Herzenberg and Dr. Vernon Oi, of Becton-Dickinson. In Germany, at the Max Planck Institute, he plans to study the genetic regulation of plants' responses to fungal infections, "a sort of plant immunology," he says.

When asked if he has considered applying his scientific expertise to studies of muscular dystrophy, Dangl turns pensive. "I have thought about it," he confides, "but I felt I wouldn't be able to distance myself from it emotionally. I would be too driven, it would just be too much," he adds.

Dangl's drive and positive outlook have taken him a long way but pursuing a graduate degree hasn't been easy, he admits. "All graduate students have moments when they think they'd like to quit and go pump gas. I've had those moments too, mostly when I've run into situations where I can't devise a system to beat gravity—it can be extremely frustrating.

He is quick to add that he might not have succeeded over the years without the help from his parents, his wife, Sarah Grant, also a geneticist, his many research colleagues, and the Rehabiliation Department.

"But you can either stay home, or you can go out in the world and see what happens," Dangl observes. "My attitude has always been that there aren't many situations that I can't figure a way out of, and that the benefits of the adventure always outweigh the hassle."

SYMPOSIUM EMPHASIZES EARLY DIAGNOSIS OF BREAST CANCER

STANFORD—

Spotting breast cancer when it is very small greatly increases chances of cure. Different ways of detecting breast cancer were among the many topics physicians discussed at Stanford's first annual breast symposium, held March 21 and 22 in Palo Alto.

Doctors "can feel cancers when they are from two to three centimeters in size. The role of imagers is to intercept the cancer at its hopefully curable state when it is less than 2 centimeters," said Dr. James Brenner, chief of the section on breast imaging at Cedars - Sinai Medical Center.

An estimated 123,900 people will be diagnosed with breast cancer this year, 900 of whom will be males. Approximately 74 percent of those will live five years or more after diagnosis. Women with a personal or family history of breast cancer are considered at risk of developing breast cancer. Some other risk factors include: not having children, not having children before age 30, being overweight, or eating diets high in fat.

Mammography, which takes pictures of the breast using X-rays, is the only proven standard imaging technique, said Dr. Ralph Smathers, Stanford's chief of mammography and coordinator for the symposium. According to Brenner, mammography can detect over 90 percent of tumors under two centimeters. It has been developed so that patients are exposed to as little discomfort and radiation as possible, Smathers said.

Some doctors believe mammography may involve a risk of radiation exposure, but "I am not terribly concerned about the radiation hazards for properly performed and interpreted mammography," Brenner said.

The risk of exposure to radiation from film screen mammography is comparable to smoking only three-fourths of a cigarette, Smathers explained. But "other modalities (of imaging the breast) are being investigated because there is a constant effort to try and find the cancer earlier and earlier," he said.

Ways of imaging the breast that are currently being investigated include thermography, ultrasound, magnetic resonance and light transmission. Thermography, which uses heat to obtain an image, may be useful as an indicator of women at very high risk of developing breast cancer, Brenner said.

Ultrasound may be used in selective cases to determine if a tumor is benign or malignant, eliminating a significant number of biopsies, Brenner said. Mammography doesn't provide this information; surgical removal of a piece of the tumor -a biopsy- is required to make this identification.

Ultrasound may also be useful as a screening method for patients with little fat in their breasts, he said. Mammography can be difficult in patients with a low fat content in their breasts, because small tumors become harder to find, Smathers said.

Light transmission technologies, if used in corroboration with mammography, may increase the sensitivity of detecting lesions and the specificity of determining malignancies, Brenner said. But, "as much as we know about the interaction of X-rays and matter, we know very little -ironically- about the interaction of light and matter," he said.

"In our experience (with magnetic resonance imaging) we haven't had a great deal of success in imaging breast cancer. My personal feeling is that we have been imaging the wrong atom," Brenner said. But, research into magnetic resonance imaging is very new compared to other modalities, Smathers explained.

So far, no other kind of imaging has proven to be a substitute for mammography, Brenner said. Techniques to improve mammographic images are also being investigated, Smathers said.

The two-day symposium, held at the Hyatt Rickeys hotel in Palo Alto, was sponsored by Stanford's Division of Diagnostic Radiology and the CGR Medical Corporation of San Leandro, Calif.

LECTURES TO FOCUS ON TRANSPLANTS, MONOCLONAL ANTIBODIES AND AIDS

STANFORD—

Sale of body parts, monoclonal antibodies in therapy and the acquired immunodeficiency syndrome (AIDS) will be discussed in three public lectures at Stanford University Medical Center this April.

"The Impact of Biotechnology on Blood Transfusion and Transplantation" is the topic of the Spring Progress in Medicine lectures, which are free and open to the community.

The presentations will be held in Sherman Fairchild Auditorium beginning at 7:30 p.m. on consecutive Tuesdays, beginning April 1.

Dr. Rose Payne, a professor of medicine and hematology at Stanford, will introduce the series. Dr. Payne's discoveries about white blood cells and the body's immunity has helped open the way to heart transplants and understanding of certain genetic diseases.

"Sale of Body Parts: New Moral, Ethical and Biotechnical Dilemmas in Transplantation" will be the first lecture, given by Dr. F. Carl Grumet, associate professor of pathology and director of Stanford University Hospital's transfusion service.

Terminally ill patients have offered finder's fees for compatible bone marrow donors, "bringing this issue to a head," Grumet explained. "Bone marrow is replaceable tissue, but what about the sale of non-replaceable tissue such as kidneys and hearts?"

After presenting a review of advances in transplantation, Grumet will raise questions about moral, ethical, political and social issues involved in transplantation.

On April 8, Dr. Steven K.H. Foung will focus on "Human Monoclonal Antibodies: Potential Use in Therapy." Once described as "magic bullets," monoclonal antibodies are tailor-made proteins that fight disease.

Foung, assistant professor of pathology and assistant director of the transfusion service at Stanford University Hospital, will focus on ways monoclonal antibodies are expected to be used to fight disease within the next three to five years.

On April 15, Dr. Edgar G. Engleman, associate professor of pathology and leading AIDS researcher, will discuss the past, present and future of AIDS, the acquired immunodeficiency syndrome.

Engleman will explain the current understanding of how the AIDS virus enters and kills cells; he also will describe possible therapies to prevent or treat the fatal disease.

Engleman is medical director of the Stanford Blood Center, associate director of Stanford University Hospital's Transfusion Service, and an associate professor of pathology and medicine at the medical school. Under his direction, Stanford became the first blood bank to test donated blood for AIDS in July 1983.

All three researchers will take questions from the floor after their presentations.

Seating is limited for the three lectures. For information and registration, call the office of Public Events, (415) 723-6389.

DEATH RATE STATISTICS FOR SCVMC MISLEADING, STANFORD OFFICIALS SAY

STANFORD—

Stanford University officials Wednesday, March 26 took issue with recently released Medicare statistics showing a higher-than-average death rate at Santa Clara Valley Medical Center (SCVMC).

Stanford President Donald Kennedy and Hospital Chief of Staff James Silverman said the statistics are "misleading" and do not indicate the high quality of care at the county hospital. Stanford's School of Medicine has a teaching affiliation with SCVMC and staffs many clinical services with educational programs.

"Valley Medical Center has been a valued partner of Stanford and we have great regard for the quality of medical care there," said the Stanford president.

Kennedy, a former Commissioner of the Food and Drug Administration, said the statistics were not conclusive enough for accurate ratings.

"I hope we will one day have at our disposal good comparative published figures on mortality rates on different hospitals for specific diagnosis and adjusted for severity," he said. "Until we have these, it seems to me premature to make judgments about particular institutions."

Silverman criticized the entire process under which the Department of Health and Human Services released the mortality figures of Medicare patients, naming 142 hospitals nationwide.

SCVMC was one of six Bay Area Hospitals with higher than average mortality rates. The statistics showed that 60 percent more Medicare patients had died at SCVMC in 1984 than would have been expected under national norms.

"The mortality rates are unrelated," Silverman said. "There's no evidence they reflect quality of care at all."

Silverman noted that SCVMC by its very nature as a teaching hospital "takes care of very complex patients and is obviously going to have a higher death rate."

The Stanford officials were not the first to challenge the significance of the federal statistics. Equally strong criticism has been voiced by the American Hospital Association and physicians. Officials at the county-owned VMC also called the figures misleading, pointing out that their hospital gets many patients who are sicker or more severely injured than are treated at some other hospitals.

Silverman said, "It's our feeling that SCVMC does an excellent job. We're aware of their physicians and their house staff and think that they're a first-class county hospital."

As for the mortality statistics, Silverman said "the problem is that aggregate data do not give you a fair snapshot of what really happens in any hospital."

He said the situation is like comparing the death rates of patients of two physicians, one of whom is a cancer therapist and the other a dermatologist. "The second one would have no deaths at all," he said.

Even comparing the same types of hospitals, such as university hospitals, doesn't give you an accurate picture, he said, "because some university hospitals treat a lot of cancer and some treat a lot of heart disease and the mortality from those two diseases varies a great deal."

Silverman said that if it were possible to "totally equalize the things you are comparing," the statistics would be meaningful. But, he said, it's almost impossible to achieve such equality because even if doctors and hospitals were the same, "the patients are different."

One patient with heart disease can be in vastly different condition than another heart patient, he pointed out.

USE OF OWN BLOOD MORE COMMON NOW, STANFORD BLOOD BANK REPORTS

STANFORD—

Autologous blood donations—units drawn from and used by the same person—have increased threefold in the last year at Stanford University Blood Bank. Currently about 15 to 20 individuals visit Stanford each week to give blood for their own use within a month or so.

"Your own blood is certainly the safest kind," acknowledged Rhoda Burns, recruitment supervisor of the Stanford University Blood Bank.

The Blood Bank has always encouraged patients and physicians to consider autologous donations, Burns said. The option, which must be ordered by a physician, has been popular in the past.

Most donations made at Stanford's blood bank, founded in 1980, supply patients at Stanford University Hospital.

Blood Bank officials attribute the increase to public concerns about the acquired immunodeficiency syndrome (AIDS) and other infectious diseases, but are quick to state that current tests effectively identify AIDS-tainted blood and that not all patients can store their own blood.

Because autologous donations must be drawn, tested and stored in advance, the procedure works best for healthy individuals who have planned elective surgery, Nathalie Finkle, RN, explained. Finkle, a supervisor at Stanford's Blood Bank, schedules and coordinates autologous donations.

Persons who are very sick, require emergency transfusions or need specialized products such as platelets can't give to themselves, she pointed out. These individuals depend on the generosity of others.

Evelyn Morrell of Menlo Park is typical of autologous donors at Stanford. Back in the Blood Bank last week for her third and final autologous donation before knee surgery in April, the senior citizen expressed her thanks for volunteer donors.

During emergency surgery a few years ago, Morrell explained, "I needed blood right away and was very glad someone else donated.

"But now I'm happy to be able to give my own blood and leave the other for someone else who needs it," she said.

Stanford University Blood Bank also accepts directed donations, blood designated for use by a particular individual.

The procedure, now accepted at most blood banks, has been controversial. Directed donations require extra handling and paperwork, boosting the cost to patients. Too, blood banks were afraid the public would incorrectly read such a move as an indication that the blood supply was unsafe.

Despite the drawbacks, Stanford decided the benefit of "alleviating fears in the eyes of the public" justified the procedure, SUBB Administrator Roger Svoboda said.

Research has shown that directed donations and regular volunteer donations are just as safe, Burns explained. "We readily accept directed donations," she said, "but we don't want patients who can't arrange them to be concerned."

Surgery in the family is stressful and blood banks don't want individuals to feel additional pressure, Burns continued. Still, people commonly become regular volunteer donors after someone in their own family needs blood, she indicated.

Stanford doesn't check blood types before donations. If a donor's blood type is inappropriate for the patient to whom he'd like to give, the donation usually goes to a patient who matches and needs it, she said.

Because of special handling procedures, both autologous and directed donations carry a higher price tag than regular blood. An autologous unit may cost only 17 percent more than an average unit of blood, but directed donations—which must be screened and tracked very closely—may cost up to 60 percent more.

Although the price may sound high—especially since the blood itself is given for free—the careful testing, typing, and cross-matching needed to ensure suitablity for a patient is costly.

Often called "the gift of life" because of its essential, irreplaceable functions, blood can cause painful and quick death transfused incorrectly.

HOSPITAL DIETITIANS OFFER WEIGHT CONTROL PROGRAM

STANFORD—

An eight-week course on weight management is being offered by the Stanford University Hospital Department of Dietetics starting next month.

Entitled "an Enlightening Experience", the course is led by registered dietitians and includes a personalized weight loss plan, low calorie cooking demonstrations, recipes, menu planning and tips on dining out, said dietitian Patricia Kearney.

Guest speakers will discuss stress reduction, behavior modification techniques and exercise, Kearney said.

Afternoon or evening classes, limited to 20 participants each, are available and are held at the Stanford Medical Center. An evening class will meet 7:30 to 10 p.m., Tuesdays, April 22 through June 10. The afternoon class meets 1 to 3:30 p.m., Thursdays, April 24 through June 12.

Kearney said the fee is $325 with a $50 refund if the individual's weight goal is reached.

Registration deadline for the first session is April 18. For further information, call 723-5432.

DESIRE FOR THINNESS PUSHES MANY TEENS TO DESTRUCTIVE EATING HABITS, STANFORD SURVEY DISCLOSES

STANFORD—

Thirteen percent of 15-year-olds report practicing purging behaviors — self-induced vomiting and abuse of diuretics and laxatives — as a means of weight control, according to a Stanford study.

Purging is associated with the eating disorder bulimia, which is characterized by a self-perpetuating pattern of binge eating followed by fasting and various methods of purging or both. Purging methods remove food from the body before it is digested.

In the survey 13 percent of 1,728 tenth-grade students from four northern California high schools reported engaging in some form of purging behavior. Female purgers outnumber male purgers two-to-one.

The survey identifies self-induced vomiting as the most common purging behavior among tenth-graders, followed by the use of laxatives and then the use of diuretics.

For most of these teenagers, purging occurred on an infrequent basis, said Joel Killen, behavioral scientist at Stanford's Center for Disease Prevention Research. Of the 10.6 percent of tenth grade girls who reported self-induced vomiting, 8.6 percent vomited on a monthly basis or less, 1.1 percent vomited weekly, and 0.9 percent vomited several times a week or more.

The survey, reported in the March 21 issue of the *Journal of the American Medical Association*, was conducted by Killen and Drs. C. Barr Taylor and David Maron, and researchers Michael Telch, Keith Saylor, and Thomas Robinson.

The rate at which these teenagers purge is probably not physically harmful, Taylor said. Most of them would not be diagnosed as bulimics because most bulimics induce vomiting in themselves at least once a day, Killen said. But, many bulimics say they began purging as teens, he said.

"What we may be seeing is the beginning of the use of unhealthy weight regulation strategies and unhealthy attitudes about weight and dieting," he said. Teenagers with these unhealthy attitudes combined with the purging behavior may be at risk of developing eating disorders that can lead to serious medical complications, Killen said.

Results of the study did not surprise Taylor "because there is so much pressure (from society) to control weight."

This survey is one of the first to document a high frequency of purging behavior in normal weight teenagers and purging behavior in males as well. This surprised Taylor because men are rarely seen in eating disorder clinics, he said.

The survey was conducted, in part, because clinics are reporting increases in the number of people -mostly females- with eating disorders, Killen said. Recent studies indicate a possible increase in bulimia in normal and overweight groups, Killen said. The actual prevalence of bulimia in the population at large is unknown, but it is associated mainly with women, he said.

3-20-86

more

The survey indicates that in contrast to nonpurgers, purgers dieted more frequently, counted calories more often, and felt greater guilt after a period of excessive eating.

Male purgers were generally fatter than their nonpurging counterparts, but there was no significant difference in weight between female purgers and nonpurgers. Female purgers reported more pronounced fluctuations in weight than their nonpurging counterparts.

An obsessive fear of gaining weight and a distorted body-image are common among bulimics, Killen said. The survey showed that attitudes of purgers are "in the direction of being more preoccupied and concerned about weight" than nonpurgers, he said.

Actually, the desire to be thin in purgers and nonpurgers may be very similar, Taylor said. But "purgers in general have more of a problem in regulation of emotions and behavior," he said.

"Sociocultural factors that link beauty, success, and happiness to a thin body shape may be partly responsible for the possible increase of bulimia," the researchers said.

"There certainly does seem to be a pressure in society to maintain a slim figure," Killen said. This pressure may lead "psychologically vulnerable individuals" to develop the binging and purging syndrome.

In follow-up studies, the researchers hope to examine possible causes of unhealthy attitudes in teens, Killen said. "That will be a major and challenging task."

Later studies will also examine how these purging behaviors progress over time and if educational intervention — such as teaching healthy eating and exercise practices and weight management techniques — has any positive impact.

Because it is very hard to get adults to change long ingrained habits "it may be more cost effective in the long run to do more primary prevention and work with adolescents," Killen said.

The survey is part of a larger Stanford study that is examining ways to change behaviors in teens to prevent coronary artery disease later in life, he said. "By changing certain lifestyle behaviors you can change your risk of developing heart disease," he said.

"The goal is to get adolescents to quit smoking, improve their eating habits, start exercising, learn symptons of stress and some ways of managing stress in their lives," Killen said.

In further studies "we will look for changes over time in variables like weight and blood pressure," he said.

PETER B GILES APPOINTED TO STANFORD HOSPITAL BOARD

STANFORD—

Peter B. Giles, 41, president and chief executive officer of the Santa Clara County Manufacturing Group, has been appointed to the Stanford University Hospital Board of Directors.

His appointment was approved March 11 by the general members of the hospital corporation. He will fill the unexpired term of Frank H. Roberts, which ends Dec. 31, 1987. Roberts, who had been a member of the board since 1970, said in his resignation letter that he felt he had served long enough.

Giles, like Roberts, is a Palo Alto resident. By-laws provide that three members of the hospital board be Palo Alto residents.

The 18-member board is comprised of community, medical and lay leaders as well as university faculty and administrators. Twelve of the members are appointed by the general members of the hospital corporation, who also are trustees of the university.

The Santa Clara County Manufacturing Group is an association of 90-member companies that employ more than 180,000 people in Santa Clara County. Giles has directed the group's attempts to provide a constructive industry approach to such issues as high housing costs, inadequate commute transportation and environmental problems.

Before joining the manufacturing group, Giles was an associate with the management consulting firm of Booz, Allen, & Hamilton, specializing in improvement projects for cities and counties.

He earned a Master of Public Administration degree in urban management from the University of Pittsburgh and a bachelor's degree in history from Brigham Young University.

MAGNETIC RESONANCE LAB TO EXPAND STUDIES INTO LIVING SYSTEMS

STANFORD—

A $1.25 million grant to enable Stanford's Magnetic Resonance Laboratory (SMRL) to expand its research to medical problems in living systems has been approved by the National Institutes of Health.

The grant from NIH's Division of Research Resources will support, in part, SMRL's activities for the next five years, said Dr. Oleg Jardetzky, the laboratory's director and professor of pharmacology at Stanford University School of Medicine. SMRL, started 10 years ago, is a national resource and its use is open also for a fee to academic researchers outside Stanford.

Most of SMRL's research until now has concentrated on chemical studies. "The expanded program is important because the whole state of magnetic resonance applications in the body is still very developmental," Jardetzky said.

The technique gives fine images of the body, but is not good enough when it comes to obtaining chemical information from deep structures, he added.

Magnetic resonance, discovered simultaneously by Stanford physicist Felix Bloch and E. M. Purcell of Harvard 40 years ago, is used to obtain information from the body both anatomically and chemically over time. It works on the basic concept that the body's nuclei contain magnetically charged particles that can be manipulated to give off signals that are picked up and interpreted by computers. The differences in the signals tell scientists precisely which structure of the body they are coming from, what the organ is made up of, and how it works on its own in relation to other organs.

The technique offers information through high resolution spectroscopy, graphs with distinct lines that show exactly how substances are processed in the body, and through the recently developed application of magnetic resonance imaging, X ray-like pictures that show soft tissue.

But while it's simple to obtain a spectrum from the head of an animal, a human arm or leg, Jardetzky explained, you can't localize the spectrum very well and you can't get anatomic or chemical information selectively from deep structures of the brain, for example.

"That's a major technical problem," he said. "Whoever solves it will open up the field to a large number of medical applications. And we as well as others have some ideas of how we can go about it."

Once the problem is solved, the scientist said, it will be possible to study the chemistry of the brain as a function of signals travelling from a sensory organ to the cortex. "This kind of mapping of the brain will be far more extensive and precise than information obtained now with the more conventional EEG," he said.

3-17-86

more

An important advantage is magnetic resonance's noninvasiveness, the scientist said. "You'll be able to study the human brain without sticking needles, without biopsies, without any kind of interference. That's the only method which can be ethically justified for getting information from a normal human brain," he said.

Three SMRL pilot projects using magnetic resonance spectroscopy have paved the way for the new applications, Jardetzky said. One of these was a study of plant metabolism done in association with Dr. Justin Roberts, now on the faculty of UC, Riverside. Another study with Dr. Eugene Robin, Stanford professor of physiology and medicine, showed how turtles sustain themselves underwater without oxygen for long periods of time.

The 1980 study, believed to be the first use of magnetic resonance in a physiological experiment, showed clearly that turtles survive underwater by a slowing down of their metabolism. The study defined the precise sequence of chemical events in cells that give the turtle this ability.

A third study with Dr. Stuart Jamieson, associate professor of cardiovascular surgery, has determined exactly how long a heart can be out of the body and still function, the best way to preserve it, and the heart's capacity to restore lost energy, Jardetzky said.

This information, he added, is important to enable surgeons to expand their donor pool of hearts, lungs and conceivably other organs as well.

In addition to its expanded scope, Jardetzky said SMRL will continue to do a very significant amount of macromolecular work. Collaborations in this area involve the departments of biochemistry, biological sciences, chemistry, and pharmacology at Stanford, as well as collaborations with scientists from the UC, Berkeley, UC, Santa Cruz and the University of Wisconsin.

Another new direction involves collaboration with Stanford's Department of Computer Science. The research involves an artificial intelligence program called PROTEAN and its development as a tool for interpreting magnetic resonance data on proteins. Computer scientists Bruce Buchanan, James Brinkley, Craig Cornelius and Barbara Hayes-Roth are studying to determine the strengths and limits of PROTEAN with protein molecules of known and unknown structure.

"In the past year we developed a completely new method for deducing protein structures from magnetic resonance data," Jardetzky said.

SMRL's equipment, he said, presently includes three NMR spectrometers—500 MHz (Mega Herz), 360 MHz, and 100 MHz. Agreement has also been reached with Bruker Instruments, a West German firm, to install a fourth instrument—a 30-centimeter bore horizontal magnet operating at 100 MHz.

The Bruker instrument, Jardetzky said, will be used primarily for magnetic resonance studies in living organisms and for the development of techniques for localizing spectra to deep structures.

SMRL's scientific activities are governed by a national advisory committee. In addition to Jardetzky, its members are Reymond Andrew, professor of radiology, physics and nuclear science, University of Florida; Erwin Hahn, professor of physics, UC, Berkeley; David Hubel, professor of biochemistry, Harvard; Martin Karplus, professor of chemistry, Harvard; Harden McConnell, professor of chemistry, Stanford; Manuel Morales, professor of biophysics, UC, San Francisco; Lubert Stryer, professor of cell biology, Stanford; and Gregorio Weber, professor of biochemistry, University of Illinois.3-17-86 —30— MRI-SA9

NERVE REGENERATION PROTEIN IS LINKED TO CHOLESTEROL TRANSPORT

STANFORD—

Scientists reported in this month's *Proceedings of the National Academy of Sciences* that they have deciphered the identity of a protein involved in nerve degeneration and regeneration.

To their surprise, the protein they have been studying for several years turns out to be apolipoprotein E, a protein that carries cholesterol and fat in the bloodstream, said Dr. Eric Shooter, professor and chairman in the neurobiology department at Stanford University School of Medicine.

The discovery may be a clue in the mystery of why damaged nerves in the periphery of the body can be repaired, but nerves of the brain and spinal cord generally do not regrow following injury.

Researchers would like to understand what controls nerve growth and regeneration in hopes of finding "switches"—genes or proteins—to turn the process on and off as needed.

The eventual goal would be to switch nerve regeneration on in patients who suffer damage to the brain or spinal cord.

Research findings on the protein, which has been studied in rats, appear in an article published in the March issue of the *Proceedings of the National Academy of Sciences*.

Shooter's colleagues and coauthors on the article are Drs. Michael Ignatius, Peter Gebicke-Haerter, and Pate Skene from Stanford; Dr. James Schilling of California Biotechnology, Inc., in Mountain View; and Drs. Karl Weisgraber and Robert Mahley of the Gladstone Foundation Laboratories for Cardiovascular Research at the University of California, San Francisco.

In its role in the bloodstream, apolipoprotein E helps ferry cholesterol and other fat molecules between cells.

Shooter and his associates believe that when a nerve degenerates after injury, the protein sponges up fat molecules that spill out of damaged nerve tissue and carries them into the cells surrounding the nerve to store the fats until they are needed to construct new replacement nerves.

Shooter and Skene originally became interested in the protein when they discovered that it was produced in relatively large quantities in developing nerves but was scarce in nerves that were not growing.

For example, the protein was plentiful in developing nerves of young rats, but not in adult animals whose nervous systems had stopped growing. One of the interesting findings is that while the protein accumulates in regenerating peripheral nerves of rats it does not accumulate in damaged brain and spinal cord nerves, which do not regenerate, Shooter said.

The research was supported by grants from the National Institutes of Health, the Spinal Cord Society and the Isabelle M. Niemela Fund.

BIOCHEMIST ROTHMAN WINS PASSANO YOUNG SCIENTIST AWARD

STANFORD—

Dr. James E. Rothman, professor of biochemistry at Stanford University School of Medicine, has been selected to receive this year's Passano Foundation Young Scientist Award.

Rothman, 35, is being honored for his work in clarifying the functions of the Golgi apparatus, a set of stacked membranes involved in regulating the flow of protein traffic inside cells.

He is scheduled to receive the award and a $10,000 honorarium at the Passano Foundation's award presentation dinner in Baltimore on Monday, March 17.

At the same time, the Foundation named the late Dr. Albert Lehninger of Johns Hopkins University and Dr. Eugene Kennedy of Harvard University co-winners of this year's senior Passano Award.

The Young Scientist Award is presented to researchers whose work demonstrates an extraordinary level of achievement early in their careers, the Foundation said. Rothman's work, in particular, has "thrown unique light on the intricacies of cellular regulation," the Foundation said.

His research has provided "the first comprehensive view of the manner in which various compartments of the Golgi apparatus modify the structure of proteins and thereby direct intracellular traffic," the Foundation citation added.

In order for cells to function, newly synthesized proteins must make their way through a maze of membranes to their proper locations. In finding a way to reconstitute the Golgi apparatus in the test tube, Rothman has been able to study the Golgi's role in this process in detail.

Rothman earned his bachelor's degree from Yale University in 1971 and his Ph.D. from Harvard in 1976. He joined the Stanford Medical School faculty in 1978 as an assistant professor, became associate professor in 1981 and full professor in 1985.

In 1984, *Science Digest* magazine named him as one of "America's 100 brightest scientists under 40."

Beginning in 1945, the Passano Foundation has presented an award each year to a person or persons who have made an outstanding contribution to the advancement of medical sciences and whose work was done in the United States. The Foundation's directors give prime consideration to work that has immediate clinical value or gives promise of practical application in the near future, the Foundation said.

Founded by the late Edward Boteler Passano, then chairman of the board of the medical publisher, The Williams and Wilkins Co., the Foundation has honored 62 scientists in the past. Eleven winners subsequently have gone on to receive the Nobel Prize. The Young Scientist Award has been presented since 1975.

Previous Stanford Medical School recipients include Dr. Hugh McDevitt, who was a Senior Laureate, and Drs. Roger Kornberg and Mark Davis, who received the Young Scientist Award.

SCIENTISTS USE NEW APPROACHES TO CURB IMMUNE ATTACKS

STANFORD—

Scientists meeting last week at Asilomar painted an encouraging picture of how the immune system one day may be prevented from turning inward to attack vital body tissues.

This is good news for millions of people with a wide variety of medical conditions, including organ transplant patients and those suffering from diseases such as rheumatoid arthritis and diabetes.

The ultimate goal the scientists seek is the ability to create tolerance, a state of truce between the body's immune system and tissues it wants to attack.

The ultimate benefit for patients is that millions of people who would otherwise face a lifetime of taking powerful and often hazardous drugs, could have the chance to lead medication-free lives.

The meeting, convened by scientists from Stanford University School of Medicine and supported by Varian Associates of Palo Alto, attracted researchers from around the world, said Dr. Samuel Strober, professor of medicine, one of the conference organizers.

Monoclonal antibodies, alone and linked to toxins, and radiation treatments are among the approaches that Stanford scientists discussed for achieving immune tolerance in patients and in animals.

Strober stressed the experimental nature of the research, but some preliminary results both in animals and humans suggest that scientists are getting closer to their long-sought goal.

In addition to the work's hoped-for clinical applications, it is also helping scientists better understand the immune system, which is normally the body's defense against disease but can become a patient's worst enemy when it mounts an inward attack on the body's own, or transplanted tissues.

Medicine has amassed a battery of powerful immune-suppressing drugs to control such immune attacks, which are called rejection episodes when a transplanted organ is the target, or autoimmune disease when the body fails to recognize its own normal tissue and launches an attack against itself.

But these medications, a lifelong necessity for many patients, have serious side effects and are extremely expensive. So scientists are exploring drug-free ways, such as tolerance, to gain control over the immune system. But they need to strike a vital balance because of the critical role the immune system plays in warding off disease.

"A requirement for immune tolerance is getting the immune system to tolerate a tissue it wants to attack without compromising its ability to defend the body from disease," Strober explained. This means that selective suppression is the key.

The scientists are using a variety of methods to try to induce selective tolerance, including radiation treatments, monoclonal antibodies, short-term drug therapy, and in the case of organ transplants, by manipulating donor tissue prior to transplant so that it doesn't trigger the recipient's immune system to attack.

One promising approach under study by Strober and his colleagues is the use of total lymphoid irradiation (TLI), a radiation technique originally developed to treat a form of cancer called Hodgkin's disease.

TLI is thought to suppress the immune system by causing a drop in number of the specific type of white blood cells that boost autoimmune attacks and transplant rejection episodes.

TLI has been administered to kidney transplant recipients, and to patients with two autoimmune diseases, severe rheumatoid arthritis, in which the immune system destroys linings around the joints, and lupus nephritis, in which the immune system attacks the body's connective tissue and kidneys. All the patients had previously failed to improve with conventional immunosuppressive drug therapy.

3-17-86

more

Strober reported at the meeting that five out of nine lupus patients have withdrawn from all drug therapy after TLI substantially improved their condition. This is in striking contrast to the normal situation, in which fewer than one in 100 lupus patients with severe kidney disease are likely to improve without chronic drug therapy, he noted.

"The question now is how long can we keep them off the drugs," he said. A disease recurrence would require them to return to medication, he explained. So far, the patients have remained drug free for periods ranging from one month to as long as three-and-a-half years without recurrence.

The use of TLI to induce improvement in rheumatoid arthritis patients has been encouraging as well, Strober said. Twenty-four of 32 patients with advanced arthritis improved significantly following TLI, but although their doses of conventional anti-arthritic drugs have been reduced, none has been weaned off medications completely.

In kidney transplant patients, TLI has reduced but not eliminated the need for immunosuppressive drugs, Strober said. In a collaborative study with Pacific Medical Center in San Francisco, Strober and his colleagues reported that most patients can avoid rejection of the foreign kidney by taking very low doses of a single drug, prednisone, rather than the usual immunosuppressive regimen which consists of larger doses of several drugs including prednisone, cyclosporine, and imuran, all expensive and likely to cause undesirable side effects.

The ability to achieve immune tolerance could also help researchers develop a new method for treating diabetes, a disease in which islet cells of the pancreas, which normally make insulin, are destroyed, cutting off the body's supply of the vital hormone.

For some time, scientists have wanted to revive insulin production in diabetics by transplanting healthy islet cells into the patient. But as with other tissue transplant procedures, rejection of the foreign cells becomes a major problem.

In new studies using rats or mice with drug-induced diabetes, Dr. Garrison Fathman and colleagues are experimenting with a double-barrelled approach to overcome islet cell rejection. In one technique, they treat the islet cells before transplantation to remove the small number of cells responsible for triggering an immune attack in the recipient animal. In another approach, they deplete the recipient's supply of the type of white blood cell responsible for rejection attacks when they transplant the islet cells.

Both methods rely on the use of monoclonal antibodies, tailor-made proteins targeted to destroy the specific type of cell the scientists aim to remove. The monoclonal antibody is attached to a toxin when pre-treating the islet transplant to destroy any immune-triggering cells.

Results with both of these techniques have been encouraging, Fathman reported. Most of the recipient animals became non-diabetic as the transplanted islet cells began manufacturing insulin. In addition, the animals have so far survived more than three months without experiencing rejection of the foreign islet cells.

Fathman and his colleagues believe they may get even better results by coupling the two techniques together. However, he stressed that much more research needs to be completed in animals before the procedures could be tried in humans.

"Even if this works as well as we hope, it would still be at least five years away from use in people," he said.

Other scientists at the meeting discussed new approaches to immunosuppressive drug use in autoimmune disease and in transplant recipients, as well as other types of studies using TLI and monoclonal antibodies. In addition, experimental attempts to induce tolerance in animals using bone marrow transplantation were discussed.

Doctors expect the number of transplant patients to soar in coming years, making control of rejection an increasingly important clinical goal.

"Part of the reason for the lack of crisp, overwhelming interest in tolerance up to now is because, by hook or by crook, people have been doing a pretty good job of getting the majority of transplanted organs to stay in for at least a year or two using drugs," Strober noted.

"But in the last analysis, the recipient would like to have something that stays in more than a year or two. We're trying to go beyond the challenge of exchanging a diseased organ for a healthy one. The meaningful thing now is how long can we get the new organ to function, and how can we do it with the fewest side effects and costs," he said.

STANFORD HOSPITAL ANNOUNCES LAYOFFS

STANFORD—

Stanford University Hospital announced the layoff this week of approximately 150 employees. The number affected were significantly fewer than had been expected when the hospital began planning the downsizing effort as part of its overall cost containment target last January.

A letter to all hospital employees from Sheldon King, president and chief executive officer, and William Arnold, vice president and chief operating officer, dated Friday, March 14, stated:

"Some 400 full-time equivalents (FTEs) have been eliminated from the 1986-87 budget. That does NOT mean that we will lay off 400 people. For several months, we have been reducing the number of FTEs by attrition—by not filling vacant positions. We have also placed careful controls on the creation of new positions."

The layoffs were part of a $25 million budget reduction outlined by the hospital in January. Before the reduction, the hospital had 4,239 employees, including those who work part-time.

In Friday's letter, employees were told: "Our managers have come up with a variety of creative ways to manage costs and eliminate expenses. As a result, the effect on our staff has been less than we had originally anticipated."

The letter noted that layoffs were not made across the board, but through an examination of the staffing needs of each hospital service.

All laid-off employees will receive at least 30 days notice. The last day of work for most will be April 11.

Most laid-off emlployees are eligible for severance pay (based on salary and length of service). There are also provisions for the continuation of some benefits.

In addition, the hospital has set up a job search center to help those employees seek new jobs. The center will provide assistance in writing resumes and submitting employment applications, list available positions in other health care institutions and offer analysis of skills and career goals.

The letter from King and Arnold concluded: "This has not been an easy time, but we have positive results to show for the work and worry of the past few weeks. We have defined a downsizing program that has the least possible effect on our employees, and now we are ready to move on—to rebuild and redefine our institution in ways that will lead us to a strong, successful future."

CHARLES E. McLENNAN, RETIRED OBSTETRICIAN, DIES AT 76

STANFORD—

Dr. Charles E. McLennan, an emeritus professor of gynecology and obstetrics at Stanford, died March 8 in Portola Valley.

McLennan, who was 76, succumbed to fibrosis of the lung after a long illness.

A memorial service will be held 2 p.m. April 5 at the First Congregational Church in Palo Alto.

McLennan joined the Stanford faculty in 1947. He served as head of his department for 26 years before retiring in 1973.

He was known for his contributions to the understanding of the function of the lining of the uterus and for work in the treatment and detection of uterine cancer.

McLennan was nationally recognized and headed several prestigious medical organizations, including the American Board of Obstetrics and Gynecology, the American Gynecological Society, the Pacific Coast Obstetrical and Gynecological Society, the Society for Gynecological Investigation and the San Francisco Gynecological Society.

McLennan is survived by his wife, Dr. Margaret McLennan, a resident of Lytton Gardens in Palo Alto; and four children: James of Rhode Island, Nancy King of New York City, Jane Stearns of Menlo Park, and Thomas of Palo Alto. Dr. Margaret McLennan also served on the Stanford medical faculty.

Before joining the Stanford faculty, McLennan chaired the department of obstetrics and gynecology at the University of Utah.

McLennan, a Minnesota native, also served on the faculty of the University of Minnesota, where he earned his bachelor's degree in 1930, his medical degree in 1934 and his doctorate degree in 1942.

From 1940-41 McLennan was a Commonwealth Fund Fellow at the University of Virginia.

Memorial contributions may be made to the Charles E. McLennan Fund for medical student scholarships, c/o Stanford Office of Medical Development, 780 Welch Road Suite 106, Palo Alto, CA 94304.

MAGNETS MAY JOIN MICROSCOPES IN DIAGNOSING DISEASED TISSUE SPECIMENS

STANFORD—

Nuclear magnetic resonance (NMR) could become a new diagnostic tool for analyzing tissue samples taken from patients during surgical biopsy, predicts a Stanford University Medical School pathologist.

It would be more rapid, and perhaps more accurate, than microscopic analysis, which is the current method for identifying infections or cancer in biopsy samples, said Dr. Steven Quay, Stanford assistant professor of pathology based at the Palo Alto Veterans Administration Medical Center.

Quay and his colleagues, Kenneth Comess, Delip Worah, and Renu Gandhi, were scheduled to report preliminary but encouraging results from a feasibility study of this use of NMR at the annual meeting of the International Academy of Pathology in New Orleans on Tuesday, March 11.

NMR recently burst onto the medical scene as magnetic resonance imaging (MRI), a new technique for viewing internal body structures to supplement more conventional X-ray images.

In MRI the patient is placed in a multi-million-dollar machine that generates a powerful magnetic field capable of rigidly aligning the nuclei of atoms in his body. Radio waves beamed at the patient "relax" the nuclei, which then emit signals that can be used to form images or to provide physiological information about body tissues.

Biopsy specimens surgically removed from a patient can be analyzed with NMR using the same basic technique but with a much smaller machine, since it doesn't have to accommodate a whole body and since images are not being formed.

Using this approach, the researchers are taking an NMR inventory of all the body's tissue types and the various kinds of tumors that can arise in them, to catalog the characteristic NMR "profile" of each.

Quay said that they have preliminary evidence that the two major types of human malignancies, carcinomas and sarcomas, have different profiles from normal tissues and from each other.

In addition, certain types of infections may be identifiable. For example, "We've got a very characteristic signal from pneumonia in the lungs," he said.

"The idea is that eventually, a pathologist might be able to put a little piece of tissue in this instrument, make a few measurements, and then make a preliminary diagnosis very quickly," Quay said.

Since NMR analysis does not alter the tissue, the sample can later be analyzed by more conventional methods under the microscope to confirm the diagnosis or to obtain additional information. "This is an unusual bonus because most diagnostic techniques do something irreversible to the tissue which prevents some further uses," Quay pointed out.

Whereas in microscopic examination, "pathologists look for patterns of abnormal tissue growth or abnormal cellular behavior, this new technique could provide a totally different kind of picture at a different level of cellular organization," Quay said.

The researchers have been using a small machine that provides more accurate information than large MRI machines because it can pick up subtle differences between tissues that imaging machines are unable to detect, he added.

But Quay stressed that there is a large amount of work to be done before the technique can be used. "It will take three to four years to fully characterize most of the important tumors," he pointed out.

If the technique turns out to be useful, however, the equipment needed is small and inexpensive enough that "many pathology departments could have one," Quay suggested.

SPECIAL CHILDREN HELP STANFORD BLOOD BANK

STANFORD—

When Lori Biagini donated blood last summer, she went home with more than a bandage on her arm: she came up with an idea.

While Biagini was giving blood, nurses in the blood bank were bundling test tubes and preparing paper bags for needle disposal. One nurse commented on "how boring it was," Biagini recalled.

"But I thought: 'What a great job for our kids!' " Biagini is a recreational therapist for retarded, autistic and disturbed children at PCC Children and Youth Services (formerly Peninsula Children's Center) in Palo Alto.

As a result, a dozen retarded and autistic children now have experience in practical work habits—and the Stanford University Blood Bank (SUBB) receives a valuable service.

"Finishing a job, paying attention to detail, and attending to tasks is easier if it's real work," explained Connie Camp, head of PCC's workshop.

Before receiving the job from the Stanford University Blood Bank, the children assembled "pretend" projects that the staff took apart at night. Now, with a real job, quality is easier to strive for and achieve, "since someone else cares," Camp said.

The children bundle three test tubes together with a rubber band; they also nest one paper bag inside another and then turn down the top edges. The tasks allow the children to practice motor skills and apply work habits, Camp observed. They also "give the kids an identity of being a worker in the community," she said.

Children sometimes accompany Biagini when she drops off finished work and picks up new materials each week.

"It's good for them to see the bags in use and see the nurses with the tubes and let them talk to the nurses," Biagini said.

Each week, more than 120 bags are used for disposal of used needles in the Blood Bank's Welch Road facility and out in the mobile unit, according to SUBB Nursing Supervisor Pauline Burn, RN. About 500 sets of bundled test tubes are needed weekly to run tests on donors' blood, she added. The children usually meet both of these quotas.

"This really saves us a lot of time," Burn said. "And these kids are not only reliable, they're consistently reliable."

Biagini, a regular donor at Stanford University Blood Bank, began giving blood four years ago as a result of a blood drive at PCC. She credits her contributions toward a co-worker's needs.

PCC Children and Youth Services provides day-time service to up to 50 autistic, developmentally delayed, behaviorally different and emotionally disturbed children from Santa Clara and San Mateo Counties. Their work with SUBB is arranged through Maureen Roskoph, SUBB's volunteer coordinator.

NEW STUDY FINDS CLUES ABOUT HOW CELLS AGE

STANFORD—

A new study, which casts doubts on widely held notions of how we age, was reported Friday, March 7, by scientists at the Linus Pauling Institute of Science and Medicine and Stanford University School of Medicine.

For years many scientists have believed that cells get older and die, in part because errors accumulate in their hereditary and protein molecules.

But according to the new findings, published in the March 7 issue of *Science* magazine, the proteins an old cell produces are indistinguishable from those of its youth, suggesting that the genetic code remains largely error-free as cells age.

A key difference between young and old cells, the research hints, may be how they use the information encoded by their genetic material, DNA.

The study, carried out in fruit flies, could have far-reaching implications for future research on the molecular mechanisms of aging in cells of higher animals, including human beings.

"We haven't solved the aging problem—we've only made a discovery that needs to be further pursued," James Fleming, research biochemist at the Linus Pauling Institute, was quick to point out. "The evidence suggests that something very subtle is going on at the genetic level as cells get old."

Fleming's colleagues on the *Science* report are Elizabeth Quattrocki, who as a Stanford undergraduate participated in these studies and is now at Yale Medical School, Klaus Bensch, professor and chairman of Stanford Medical School's pathology department, and scientists from the Linus Pauling Institute, including Gerald Latter, a computer specialist, Jaime Miquel, a research associate, Rick Marcuson, a biostatistician, and Dr. Emile Zuckerkandl, director and president.

The researchers chose to study flies because cells in the adult insects cease dividing, providing a population of cells that are almost all growing old at the same rate.

"Nearly every cell in the tissues of a 40-day-old fly is 40 days old," Fleming explained.

Cells of the human body that similarly do not divide or renew themselves—many cells in the brain and heart, for example—are thought to be important factors in human aging, Fleming explained in an interview.

Although compared to a person's lifetime, the month-and-a-half long lifespan of a fly seems short, "we assume that what goes on in a fly is similar to what goes on in the non-dividing cells of higher animals," Fleming said.

-more-

3/10/86

The researchers used a technique called quantitative two-dimensional gel electrophoresis to look for age-related changes in a large fraction of proteins found in fly cells.

Since proteins are the molecules that carry out cell activities, alterations in their structure could bring about significant changes in a cell's ability to function. In addition, since the blueprint for proteins is encoded in the DNA, changes in protein structure would probably reflect errors, or mutations, in the cell's genetic material.

They found no evidence of any alterations in the proteins they examined as the insects aged from young (10-day-old) to middle-aged (28-day-old) to old (44-day-old).

But the researchers did find that some of the proteins are produced in vastly different quantities at the various stages of life.

"The things that go wrong in aging appear not to be associated with changes in molecules, but are instead changes in the synthesis rates of individual proteins," Fleming said.

He added that for some time people have known that overall protein synthesis slows down in aging cells. The new findings show that the decrease in synthesis is not uniform, Fleming added.

"The synthesis of some proteins increased, for others it decreased, and for some it didn't change as the cells aged," he noted. "We do not yet know the identities of most of these proteins, but one of our next steps is to try to find out. It could be important for understanding what happens during aging to identify some of the proteins that have dramatic changes in their rates of expression."

The finding appears to contradict several hypotheses about aging, including the "error catastrophe theory" which holds that an error in a key protein can quickly become amplified. For example, if a protein involved in making other proteins becomes defective, it could cause a cascade of defects among proteins throughout the cell.

The report also raised questions about other hypotheses of aging, all of which revolve around the idea that mutations in a cell's DNA lead to flawed proteins that accumulate in the cell, hindering its ability to function.

"We don't know what's going on, but whatever it is, it's subtle—it's certainly not a catastrophe," Fleming said, "and it appears not to be a result of mutations in genes that code for many proteins."

The research was supported in part by a grant from the Glenn Foundation for Medical Research.

DIABETICS NEEDED FOR RESEARCH STUDY

STANFORD—

Diabetics can obtain a comprehensive free physical examination while helping researchers at Stanford University Medical Center test a new medication.

Dr. Elizabeth Fraze, a fellow in endocrinology, said at least 20 adults between 40 and 70 years are needed for the study, which will be determining the effectiveness of a new medication, Linogliride. Fraze said the medication could reduce or eliminate varied side effects, such as reddening of the face, for some patients if proven effective.

Volunteers must have Type II adult onset diabetes but be otherwise in good health, said Fraze. She added that participants may or may not be taking insulin but must be willing and able to give up that medication while taking the new oral medication during an approximately six-month trial.

The physical exam will include an evaluation of kidney and liver function, cholesterol level and an electrocardiogram.

The study is headed by Dr. Fredric Kraemer, director of the medical center's diabetes clinic. For further information or to volunteer, contact Fraze or Kraemer at (415) 497-5947 or 497-6054.

About 80 percent of the estimated 5.5 million diabetics in the United States suffer from Type II adult onset diabetes mellitus, a metabolic disorder in which the body fails to process carbohydrates properly. Strict attention to diet and medication are common treatments.

CLASS SCHEDULED FOR PSORIASIS PATIENTS, FAMILIES

STANFORD—

Psoriasis patients and their families will have an opportunity to learn about the chronic and often debilitating disease at a one-day workshop scheduled March 15.

The workshop is to cover such topics as cause and course of the disease, treatment, preventive measures, myths and current research, said Dr. Lexie Nall of the Stanford Medical Center Dermatology Department, which is co-sponsoring the event with the Psoriasis Research Institute.

The free session is scheduled from 10 a.m. to 4 p.m. at the Psoriasis Research Institute conference room, 600 Town and Country Village in Palo Alto.

The need for workshop sessions are important for psoriasis sufferers because the course of the disease is unpredictable, and recurring flareups can be particularly stressful for patients and their families, Nall explained.

For further information, contact Nall at (415) 497-7967.

PUTTING THE HEAT IN CANCER

STANFORD—

An ancient idea is back. Combined with radiation, development of better equipment and understanding of its biology, heat could gain an important place in the armory of weapons against cancer.

It all began with fever. Ancient peoples believed it cured illness. In the late 1800s, reports appeared that patients with cancer were cured after becoming sick with smallpox, pneumonia and malaria. Searching for answers, some doctors speculated that fever, which accompanied the illnesses, might have been responsible.

Scientists all over the world have since tried, with varying success, to use heat to treat tumors in patients. They have used low and high frequency currents, carbon lamps, infrared heaters, hot baths—even methods to induce fever. By 1950 mouse tumors heated by microwaves could be destroyed without damaging the animals. And studies in dogs and man showed that in some instances cancers could be selectively reduced by heat without damaging adjacent tissue.

"Today hyperthermia (heat therapy), used in combination with radiotherapy, offers a hopeful option to patients with surface cancers and their physicians when all else has failed," says Dr. Daniel Kapp, director of Stanford's clinical hyperthermia program.

In studies, heat alone produced complete shrinkage of surface tumors in 15 percent of the patients treated, but the effect was short-lived. When hyperthermia treatments were combined with radiotherapy, however, the response rate improved dramatically. Kapp and his colleagues have reported a 73 percent response rate in patients treated for superficial lesions with heat and low to moderate dose radiation.

"Heating tumors increases their sensitivity to treatment with radiation," explains Dr. George Hahn, a radiobiologist and hyperthermia pioneer at Stanford. "Heat increases the permeability of cell membranes and cells may appear to be less able to repair damage to DNA. When heat disrupts the repair process, you can use radiation to kill tumor cells more effectively."

Hahn and his colleagues have shown similar effects in animal studies by combining heat with common anticancer agents adriamycin and bleomycin. Their research has paved the way for studies in which hyperthermia will be combined with chemotherapy to achieve enhanced tumor-killing.

But for the time being, Kapp and his associates are treating tumors on the surface of skin or under the skin with temperatures up to 44 degrees centigrade. Most available microwave or conventional ultrasound heat sources often can't get any deeper in a predictable, controllable manner, they have found.

"Another reason for concentrating on surface tumors," Kapp explains, "is that you can safely monitor their response and toxicity (burns) to adjacent tissue. It's tougher to get temperature data from deep-seated tumors unless you use more invasive procedures."

Surface lesions treated with hyperthermia by the Stanford team are usually squamous-cell tumors, often the result of metastasis from oral and head-and-neck cancers, and malignant melanomas that can appear anywhere on the skin. "But its most important application is in chest wall metastasis from breast cancers, which has been difficult to manage in any other way," points out radiology chairman Malcolm Bagshaw.

Kapp estimates that despite chemotherapy and radiation therapy, chest wall recurrences develop in up to 20 percent of patients with breast cancer, representing as many as 20,000 patients a year in the United States alone. Such patients can't tolerate additional high radiation doses because of tissue damage from previous treatments. But with the combined heat and radiation treatment, "we can often get a complete response," Bagshaw adds.

more

Stanford's clinical studies began more than five years ago with patients with chest wall cancers for whom conventional therapy had failed. "Their cancers had already spread outside the areas that could be treated with curative therapy. It was with such patients willing to participate in our studies that the combined therapy could be ethically justified," Kapp says. In most patients who later died of their disease, heat treatments produced a palliative effect. Some are still living. But overall results were so encouraging that hyperthermia in combination with radiation will become a front-line treatment for such patients. It will also be extended to others with less metastatic cancer, Kapp predicts.

Knowing if the tumor is heated uniformly is the key in hyperthermia, experts agree. Medical physicist Dr. Thaddeus Samulski explains: "We can't deliver heat as consistently as we'd like with the type of equipment and controls now available. The body has built-in mechanisms to compensate when tissues are overheated. Blood vessels dilate and circulation increases to cool the tissue. The problem gets really complicated when you consider that a tumor often contains different tissues and heterogenous areas of blood flow.

"We have physiological variables to overcome. They outmatch our equipment."

Another target for hyperthermia study is low pH and the lack of adequate nutrients including oxygen. Decreased oxygen and low pH, a measure of acidity in cells, dramatically sensitize tumors to heat treatment. Hahn is looking for ways to manipulate this concept in order to increase tumor sensitivity to heat. If he succeeds, some believe, one might destroy tumors more efficiently in spite of present equipment limitations.

Under the direction of Kapp and physicist Dr. Peter Fessenden, a Stanford group of physicians, physicists, engineers and biologists have teamed up to grapple with the technical challenges. They are developing, refining and evaluating instrumentation for generating and controlling high temperatures in the human body. Part of this work is funded by the National Cancer Institute in a project which includes three other centers: the University of Arizona, University of Utah, and M.D. Anderson Hospital in Texas. A new NCI grant to Stanford for further equipment development is also expected to be funded soon.

The activity is centered in the Virginia and Dean Morrison Hyperthermia Suite in the basement of Stanford's hospital. Cluttered with computers and monitors, it is the place where patients are treated. Under console control, an oscillator generates microwaves. They are amplified and transmitted to an antenna or heat applicator in the treatment room, shielded with copper screen to prevent radio interference. The patient, lying on a gurney, receives the microwaves delivered by the applicator. Heat sensors implanted on and under the skin show on a color TV screen that the heat is reaching the targeted tumor.

"A heat applicator must allow energy to pass into the tumor efficiently," says Samulski in explaining the difficulties. "This isn't simple when you try to get it into tissue with different electrical or acoustic properties."

Because existing applicators are inefficient and limited in size, Stanford researchers are collaborating with Varian Associates in Palo Alto to develop better ones. "Varian designed one that's more conducive for clinical use," Samulski says. "The applicator is more amenable for placement on areas of the body. Moreover, several applicators powered individually could be used to heat larger regions, particularly when scanned over the surface."

Another improvement was to add a water interface between applicator and skin to achieve better contact, permit cooling of uninvolved skin and prevent accidental decoupling during treatment.

"The next step in our hyperthermia equipment development will be robots," Samulski predicts. "Robots may be useful because heating large tumor areas requires moving the applicator in repetitive motions for an hour, a difficult task for a person to do accurately." Engineer Eric Lee is adapting a robotic arm to scan heat applicators by computer control.

The team is also looking into alternate methods for heating tumors, such as ultrasound and interstitial hyperthermia. Both offer promise for the next step—local treatment of deep-seated tumors.

more

Interstitial hyperthermia, developed by Drs. Don Goffinet and Stavros Prionas, combines two techniques relatively new to cancer therapy. Seeds of radioactive iridium-192 are embedded in ribbons. Both the radioactive seeds and heat are delivered by means of slender, hollow tubes temporarily placed into a patient's tumor. Ionizing X and gamma rays emanate from the ribbon seeds inside the tubes. Heat is produced by radio frequency waves pulsed through a metallic grid that coats the outside of the tubes. An insulating sheath coating the grid permits researchers to heat only the targeted cancer, sparing healthy tissue. Sensors in the tumor relay temperature information to a computer that controls radio frequency pulses generated down each tube. The computer is set to keep the tumor volume evenly heated at the selected temperature. The monitoring and delivery system was developed by Prionas. The special tubes were developed in collaboration with Oximetrix, a Mountain View-based company.

So far 10 patients with head-and-neck, colon and rectal cancer have been treated with the experimental technique. Goffinet reports that with some patients there have been"impressive" results. However, he cautions, interstitial hyperthermia is nowhere near being considered standard therapy.

"The technique gives you a handle on what you're heating or you're not," Samulski comments, "but it's terribly invasive. So there's the tradeoff."

Ultrasound was the earliest method of heating tumors tried in patients in combination with radiation by Hahn and oncologist Dr. Jane Marmor at Stanford. One patient, Bagshaw recalls, was a bald-headed man in his fifties whose cancer of the larynx had metastasized to form two scalp tumors. One vanished after hyperthermia plus radiation treatments, but the other tumor treated with radiation only did not completely respond and promptly grew back. Similarly, partial remissions were recorded in 54 percent of 25 patients with squamous-cell cancers.

"The advantage of ultrasound is that you can focus it. You can deposit the heat where you want it," Hahn says. "For some deep-seated tumors, ultrasound works very nicely. But it doesn't penetrate air tissue such as the lungs, for example. And it's deflected by bone. There are few areas in the body where you can get it to work."

Ultrasound is also painful when it heats bones. Hyperthermia researchers have been reluctant to use anesthetics, however, because pain warns them when some tissue is getting excessively heated. Also, heat may make certain topical anesthetics increasingly toxic. "Pain is something to be reckoned with," Fessenden says. "If ultrasound is going to work for deep heating, it must have tremendous flexibility and control precision. This must be coupled with a sophisticated imaging system that allows you to know which tissues you want to heat or miss."

Another approach to heat deep tumors being tested is the Annular-Phased-Array, developed by BSD Corporation in Utah. It consists of 16 radiating elements in a drum with a hole in the middle where the portion of the patient's body to be heated lies. The machine's microwave energy can be synchronized to heat deeper areas with enhanced effect. Samulski describes it as a "dump and pray approach. You dump in the energy and you pray you've heated the tumor," he says. "It's a crude way of doing it, but it avoids some of the problems of ultrasound."

As hyperthermia evolves, another concern worrying its practitioners is cost. "Hyperthermia is much more labor intensive than radiation therapy alone," observes Fessenden. "You're lucky if you can finish a treatment session in two hours. That includes getting the patient ready, placing the temperature monitoring probes, delivering the heat, removing the probes. The same treatment with radiation can be done in ten minutes." So another project is trying to determine how hyperthermia combined with radiation can be cost-effective. For example, are two hyperthermia treatments as effective as six? "We're comparing and analyzing the statistical difference," he says.

As for fever, which has given hyperthermia its start, science is beginning to zero in on that puzzle, too.

"The function of fever can now at least be partly explained in molecular terms, proving that the intuition of our ancestors was right all along," muses Hahn. "Recent published studies have shown that if you heat tissue, the cells make heat-shock proteins in competition with production of viral proteins. The reduced synthesis of viral proteins inhibits virus multiplication. This must clearly be one purpose of fever."

Whether this finding will lead also to an elaboration of the molecular basis of hyperthermia and its anticancer properties could be the next chapter in Hahn's research. "Some of the heat-shock proteins participate in determining a cell's purpose and function," he explains. "We're looking at how fever may actually modify differentiation patterns of cells responsible for immune responses and how heat could enhance them, hopefully to fight cancer."

4-4-4

A HYPERTHERMIA PIONEER

Austrian-born George Hahn, 59, is considered the father of the hyperthermia research program at Stanford. A microwave physicist-turned cellular radiobiologist after his son died of cancer in 1962, he has done much of the basic laboratory research that has given hyperthermia the status it has today.

Ironically, Hahn's work didn't start with heat. "We were looking for ways of inhibiting damage induced by radiation," he recalls. "We tried drugs but they were so toxic they were useless."

So Hahn shifted his research to cold. Temperatures of 4 degrees centigrade inhibited repair, he found, but only as long as cells were kept cold in his laboratory dishes. Why repair? "Because after radiation, you don't want cancer cells to start repairing themselves and forming new colonies," he replies.

Next, Hahn tried heat. To his surprise, it permanently inhibited repair. "But we also found other interesting things," the scientist remembers. "Some aspects of cellular response to heat are unique. If you heat cells nonlethally, return them to the host temperature of 37 degrees centigrade and heat them again, they become remarkably heat resistant.

"Such cell behavior," Hahn admits with a gleam in his eye, "makes hyperthermia treatment more difficult, but it also makes the biology more interesting." As part of this development, called thermotolerance, it seems that specific proteins are synthesized and very likely play a role in this protective effect. "What's even more remarkable about thermotolerance," Hahn adds, "is that bacterial yeast and insect cells give a similar response. The proteins involved are conserved over the cell's evolutionary development."

These "heat-shock" proteins, Hahn thinks, are associated with differentiation, the process that gives cells their characteristics during the organism's development. "An entire new area of thermobiology has opened up as a result of these studies," he says, "and several laboratories are now trying to determine how heat activates the process at the molecular level."

In 1976 Hahn gained some local fame among pet owners when he and Dr. Jane Marmor, now with the Palo Alto Medical Clinic, began treating cancer-ridden pets with ultrasound heat. The results were encouraging, and the word got around fast in the pet community. People who noticed nasty looking sores on their dogs and cats began to bring them to Hahn for treatment.

"George is getting way ahead of us," says radiology chairman Malcolm Bagshaw, whom Hahn calls one of his mentors along with the late Henry Kaplan. "For example, he's demonstrated that drugs are also enhanced by heat, but we haven't had the time to put in our studies all three elements—hyperthermia, chemotherapy and radiation—together."

Among those influenced by Hahn is Daniel Kapp, now director of Stanford's hyperthermia program. As a resident, Kapp did research in Hahn's lab. They found that certain drugs that are not normally considered harmful become toxic under hyperthermia. Being aware of this problem may prevent complications in patients undergoing heat treatments. And, such compounds selectively delivered to heated tumors may be useful as adjuvants in cancer therapy.

Hahn's work spans more than 150 publications and a book, *Hyperthermia and Cancer.*

ADVANCE FOR RELEASE 3 P.M. PACIFIC TIME, WEDNESDAY, MARCH 5, 1986

EXERCISE IS LINKED TO LONGER LIFE IN STUDY OF HARVARD GRADUATES

STANFORD—

A joint Stanford/Harvard study of nearly 17,000 Harvard alumni has revealed that physically active men live an average of slightly more than one to two years longer than their sedentary counterparts.

The report, published in the March 6 issue of *The New England Journal of Medicine*, is believed to be one of the first scientific studies linking increased longevity to an active lifestyle.

The study does not fully explain why active men live longer, although it appears to be a result of reduced cardiovascular and respiratory disease in the alumni who exercise, said Dr. Ralph Paffenbarger, the Stanford epidemiologist who led the study.

Paffenbarger is professor of epidemiology in the department of family, community and preventive medicine at Stanford University School of Medicine. His colleagues on the study are Robert Hyde, a Stanford epidemiologist, Alvin Wing, a statistician-programmer in the department of epidemiology at Harvard's School of Public Health, and Chung-cheng Hsieh, an epidemiology faculty member at the Harvard School of Public Health.

The study was funded by grants from the National Heart, Lung and Blood Institute, the Marathon Oil Foundation, the G. Unger Vetlesen Foundation, and the E.I. du Pont de Nemours Company.

The researchers were careful to point out that the study does not prove that exercise prolongs life, nor did it answer the question of whether a change in lifestyle, from sedentary to active, can prolong life. What it did show is that the Harvard men who habitually spent approximately three or more hours per week exercising lived longer, on the average, than those who rarely exercised.

The results also showed that the alumni who lived longer were those who remained physically active after graduation. Men who had been very active in sports during college but later became less active or sedentary did not live as long as those who exercised moderately throughout life.

The increased length of life associated with regular exercise was seen across all age groups. In all, ten percent more of the active men survived to age 80 than did their less active classmates, according to the study findings.

The increased survival associated with exercise was found to be independent of factors associated with a shortened length of life, such as cigarette smoking, high blood pressure, extremes of body weight, and family history of early death, the researchers reported.

The study followed 16,936 Harvard alumni, aged 35 to 74, for a period of 16 years. In addition to college and medical records made available to the researchers, participants answered questionnaires about their personal health habits, including how many hours per week they spent in various types of sports and other physical activities. There were 1,413 deaths during the follow-up period.

Paffenbarger, who exercises regularly, said in an interview that at first he was personally slightly disappointed to learn that a physically active lifestyle is associated with only about two additional years of life. "I would have guessed that it would have been longer," he confessed.

more

But Paffenbarger and his colleagues stress that the public health implications of the study's findings are significant. "If we completely eliminated cancer as a cause of death, years of life gained would be about the same—Americans would live on the average only two years longer," he said.

The researchers hope the results will not provide an excuse to stop exercising to those who don't enjoy it. "Two years is a long time," he said. "Our computations suggest that for every hour the active graduates spent exercising, they lived that hour over, plus an extra one or two hours," Paffenbarger said.

In addition, the researchers pointed out that being physically active often improves the quality of life, no matter what the overall length of life may be.

Other results from the study suggest that smokers and those with high blood pressure are at greatest risk of death, but that being physically active can lower this risk.

The study also revealed that graduates who had a net weight gain of more than 15 pounds after college lived longer than those who gained less than 15 pounds. This was a surprise to the researchers, since the men who gained more weight were at greater risk for cardiovascular diseases, which can lead to death from heart attack and stroke.

However, they believe that the low-weight-gain group didn't live as long because "this represents a group of people who eventually die from wasting conditions such as cancer, neurological diseases, and perhaps diabetes," Paffenbarger said. "The leanness that is frequently associated with cigarette smoking is not a sufficient explanation."

Since the study was restricted to Harvard men, the results should be extended to the entire population at large only with caution, the researchers said. "The Harvard alumni may not be typical of the general population," they noted. "The bulk of these men are cut from the same cloth—intelligent, educated and affluent," Paffenbarger said, "and in general, they live longer than the average Caucasian American of comparable age."

The results also are inconclusive for women, although Paffenbarger noted that epidemiological studies identifying characteristics predictive for heart disease have revealed the same ones for men and women. "So, if you had to guess, you'd probably suggest that these results hold for women as well as for men," he said.

"Another question that remains unsettled is whether vigorous exercise is the only kind of physical activity associated with increased length of life," Paffenbarger said. The study only examined each man's energy output per week during activities such as walking, stair-climbing and sports, but did not measure heart rates achieved or other indicators of effort. Vigorous activity is known to be important in improving cardiovascular fitness, Paffenbarger said.

Previous findings from the same follow-up of Harvard alumni have shown that habitual exercise has a beneficial effect in lowering blood pressure, and that it is associated with a reduced incidence of cardiovascular disease, including heart attack.

Paffenbarger noted that the researchers are planning to examine, in the same overall group of Harvard men, whether or not changing from a sedentary lifestyle to an active one is associated with increased longevity.

This debate over the benefits of exercise in lengthening life, which started in antiquity, has been going on and will probably continue for some time, Paffenbarger said. "People back in the 1700s showed that tailors did not live as long as farmers, presumably because the tailor was inactive and the farmer was active."

ANTISMOKING PROGRAMS WITH VARIETY PROVE EFFECTIVE IN COMMUNITY STUDY

STANFORD—

Stop smoking programs can significantly reduce cigarette use throughout a community but a variety of educational approaches are needed, a more than four-year study in four California cities has disclosed.

Smoking decreased 11 percent more among men and women aged 25 to 74 in the two cities where an aggressive education campaign was mounted, said Dr. Stephen Fortmann, associate director of the Stanford Center for Disease Prevention (SCRDP), which conducted the study. He was scheduled to present his results, which are preliminary, Tuesday, March 4 at the American Heart Association's 26th annual conference on cardiovascular disease epidemiology in San Francisco.

In 1979, before the concerted education effort was launched, smokers in the education cities of Monterey and Salinas numbered about 29.9 percent of the population. This closely paralleled the national average of 30 percent. After four and half years, the smoking rate had dropped to 20.3 percent of those who continued in the survey, Fortmann said.

In the reference (control) communities, Modesto and San Luis Obispo, 28.9 percent of the population were smokers in 1979. By the end of the study, 22.7 percent of survey participants continued to smoke.

Because of the nature of the survey, Fortmann said the true decline in smoking rates was probably less than reflected in the figures, but the difference between the education and reference cities should hold up. Other survey results are still being analyzed to further evaluate the program, he added.

"Statistically, there's a net difference of 11 percent between the towns where there was an education campaign and the two towns where there wasn't. In human terms, that means less cancer and heart disease, less heartbreak for individual families," Fortmann said.

In the study, Monterey and Salinas were provided with a variety of anti-smoking programs, including a massive television and newspaper education campaign on the dangers of smoking, group therapy, contests with a free trip to Hawaii offered as a prize to a smoke quitter, and educational kits distributed to individual smokers.

In Modesto and San Luis Obispo the surveys were conducted, but no education programs were initiated.

"We found that some types of programs worked better than others but that all types of programs were needed for an overall effective community effort," Fortmann said.

For example, Fortmann noted that the support groups were most effective. Twenty-five percent of the participants, numbering about 500 per year in each community, were still off cigarettes after six months. About 11 percent of the persons using the quit kits, which offered a step-by-step stop smoking plan for individuals, were still off cigarettes after six months, said Fortmann.

3-3-86

more

"One could argue that because the groups were more than twice as successful as the kits, that you should concentrate only on that approach. But what we found was that in total numbers, a lot more people—about 5,000 per year in each community—were using the kits.

"And some people simply wouldn't go to a group, or if they did, they wouldn't be comfortable with that approach. And for that segment of the smoking population, the quit kit represented a viable—and perhaps unique—alternative to smoking," Fortmann explained.

The researcher noted that techniques such as the quit kits are economical, costing about $18 per person, which is far less money than medical costs associated with continued smoking.

He noted that other efforts, including television and newspaper messages, may have had an effect both on getting people to stop smoking and on spreading the word about groups and other aids to quitting.

The free trip to Hawaii, offered by local business in Monterey and Salinas, seemed to be particularly successful at publicizing the anti-smoking message, Fortmann said. Persons who signed up for the contest and successfully quit smoking were eligible for the prize drawing.

About 650 persons were surveyed as to health habits, including smoking, in each of the four cities. An effort was made to survey the same persons four times between 1979 and 1984 to record any changes in health or behavior.

"Smoking dropped in all four communities, and that was both positive and a sign of the decline of cigarette smoking in our society," said Fortmann.

"What was significant was that the educational programs had a measurable effect at encouraging smokers to kick the habit over and above the decrease in smoking already taking place," Fortmann said.

The project was funded by the National Heart, Lung and Blood Institute, which annually provides $1.7 million in funding for SCRDP's Five Cities Project, a study of community health and education intervention which included the current smoking study.

Fortmann said that the communities had been carefully selected to be comparable. One of the education communities, Salinas, and one of the reference communities, Modesto, were agricultural service towns. Monterey, an education community which is a resort center, and San Luis Obispo, a college town which served as the second reference community, both had similar income and education levels.

Results are still being analyzed, but Fortmann said several trends appeared to emerge from the study. Women, he said, are more likely to quit, and perhaps not surprisingly, quitting was harder for the heaviest smokers.

Currently, SCRDP is studying special techniques for heavy smokers in the education communities and elsewhere, including physician involvement and the use of medication such as nicorette gum as an aid for the most seriously addicted smokers.

The survey and education efforts involved the smoking habits and potential exposure of children as young as 12, and results of special prgrams to discourage teen-age smoking are still being analyzed, Fortmann said.

Other researchers involved in the project included June A. Flora, Ph.D., education director of SCRDP; Dr. C. Barr Taylor, a psychiatrist and behavioral science director of SCRDP; and SCRDP director, Dr. John W. Farquhar.

DIET, EXERCISE EQUALLY EFFECTIVE IN IMPROVING CHOLESTEROL AND BLOOD PRESSURE LEVELS, STANFORD STUDY SHOWS

STANFORD—

Losing weight only by dieting or only by exercising are equally effective in improving cholesterol and blood pressure levels, a new Stanford study has shown.

Each weight loss method was found to similarly increase levels of high-density lipoprotein (HDL), the so-called "good cholesterol" believed to help prevent heart disease. At the same time, each method similarly reduced blood pressure levels, said Dr. Peter Wood of Stanford's Center for Research in Disease Prevention (SCRDP).

While either method is effective, the researchers concluded, a weight loss program combining both diet and exercise is the optimal approach for physical as well as physiological benefit.

Wood and SCRDP co-investigators Drs. Stephen Fortmann and William Haskell presented their findings at the American Heart Association's 26th Annual Conference on Cardiovascular Disease Epidemiology in San Francisco Monday through Wednesday (March 3-5).

The study, funded by the National Institutes of Health, looked at changes in cholesterol levels and blood pressure levels to see how they were affected by different methods of weight loss. The researchers were suprised, Wood said, to learn that the effects were similar.

"Exercise has the advantage of minimizing loss of body muscle, relative to the diet approach, while it enables the loser to maintain caloric and nutrient intake and also to gain the established health benefits of regular exercise," the researchers concluded. "However, it is clear that increased exercise is not an essential component of weight loss" to achieve beneficial changes in cholesterol and blood levels.

The researchers placed 155 generally healthy but moderately overweight—between 20 and 50 percent above the ideal weight—men into three groups. The exercise-only group did not change their eating habits, but increased their exercise to an average of jogging about 10 miles a week. The diet-only group did not increase their exercise amount, but decreased their caloric intake by about 300 calories a day. The control group did not change their diet or exercise habits at all.

Each participant was monitored for a year. The diet-only group lost an average of about 16 pounds, while the exercise-only group lost an average of about 10 pounds. However, Wood pointed out, the percentage of body fat of participants in both groups remained similar. This, he said, is a more accurate measure of actual loss of body fat.

Participants' levels of HDL, the type of cholesterol that may help prevent heart disease, significantly increased and levels of low-density lipoprotein (LDL) tended to decrease regardless of which weight loss regimen they followed, the researchers found. However, while the HDL levels of those in the exercise-only group increased in direct relation to the number of pounds they lost, the HDL levels of those in the diet-only group did not correspond in the same direct relationship but rather in a much more random manner. This, Wood explained, suggests that factors other than weight loss are involved in cholesterol level changes.

"We plan to pursue these unknowns," Wood said.

The different weight loss methods had similar effects on blood pressure levels as well, Haskell added.

The researchers found that participants' blood pressure levels decreased an average of five percent in real life situations—a meeting at work, a relaxing evening at home or a weekend bike ride, for example. The decrease was not detected when participants underwent testing in the laboratory, possibly because it is an artificially controlled setting, Haskell said.

"This is the first time physicians have been able to look at the effects of weight loss on ambulatory blood pressure levels," he explained.

Participants wore specially designed electronic recorders that monitored their blood pressure levels every 20 minutes all day long. "This supports the generally held notion that weight loss does provide positive effects in lowering blood pressure," Haskell said.

HOSPITAL SPONSORS SHOPPING CENTER HEALTH FAIR

STANFORD—

Stanford health information is being taken shopping from 10 a.m. to 4 p.m., Saturday, May 17 at the Third Annual Stanford University Hospital Health Fair.

"Help Yourself to Health" is the title of this year's event at Stanford Shopping Center in Palo Alto.

Hospital Community Outreach Coordinator Linda Romley-Irvine said the event features free blood pressure checks and counseling, as well as a free cardiac risk factor analysis.

Various hospital departments and services will be staffing booths to help the public understand the range of sevices offered by the hospital, she said.

Among topics available in the booths are diabetes, the Life Flight emergency transport service, Home Care, surgery and operating room, as well as information on the new Trauma Service.

All booths, located in the pavilion area near the center of the shopping center, are free and open to the public.

EXPERTS OUTLINE POSSIBLE MEDICAL CONSEQUENCES OF CHERNOBYL NUCLEAR ACCIDENT

STANFORD—

Both short-term and long-term medical consequences can be expected as a result of the Chernobyl nuclear reactor accident in the Soviet Union, two Stanford University medical experts agree.

The short-term effects will be the result primarily of acute radiation sickness and possibly of burn or blast injuries, while longer term effects will be the result of exposure to radioactive fallout and consumption of radioactive materials that enter the food chain, the two scientists predicted.

But the many remaining unknowns in the situation make it difficult now to accurately predict the extent of medical and environmental damage, according to Dr. Herbert Abrams, professor of radiology and Dr. Roland Finston, director of health physics at Stanford University and lecturer in radiology.

Abrams is a co-founder of International Physicians for the Prevention of Nuclear War. Both he and Finston are experts on radiation exposure.

"Many variables determine the amount and type of radioactive elements released, and their spread through the environment," Finston explained. "The operating history of the nuclear reactor and the age of the fuel will affect the release," he said. The temperature of the fire that is consuming the fuel can also make a difference, he said.

None of this kind of information has yet been released by Soviet authorities.

At lower temperatures, radioactive iodine will be released and as the temperature gets hotter, other radioactive elements such as cesium, strontium, tellurium, and ruthenium can escape, the scientists said.

Reports from Scandinavia have already indicated the presence of these elements in the radioactive cloud.

Radioactive iodine can accumulate in the thyroid gland where, in large amounts it can cause thyroid tissue damage that reduces the gland's activity, and eventually may cause nodules to form or even thyroid cancer, Abrams explained. Radioactive iodine has a relatively short half-life, which means that half of the released volume will have decayed within eight days.

Cesium, strontium and some of the other elements are more likely to harm tissues in the body that have rapid turnover of growing cells, such as the gastrointestinal lining and the bone marrow, Abrams and Finston explained.

These elements, which have longer half-lives of up to 30 years, are capable of penetrating the food chain for years to come in the areas where the radioactive fallout reaches the ground, Finston said.

The worst radioactive release would be of trans-uranic elements such as plutonium, which has a half-life of 25,000 years, Abrams noted, although there is no evidence that this has occurred in the Chernobyl disaster.

The magnitude of the fire and weather patterns will determine where the radioactive plume spreads, Finston said.

A mammoth explosion could lift radioactive particles high into the atmosphere where they have a greater chance of spreading rapidly, Finston said. But a fire probably cannot hoist the radioactivity into the stratosphere, he said.

Both Abrams and Finston agreed that there is little danger that medically hazardous levels of radioactivity will reach the United States because the cloud gets diluted as it moves away from the reactor site.

But regions closer to the the Ukraine, the site of the accident, may be affected. "A lot depends on the weather patterns," Finston explained. If it rains in an area where the radioactive cloud is present, the raindrops carry the particles to the ground. "This would cause a more intense deposition of radioactive particles under the area of rainfall," he said. Wind patterns also are important factors in the plume's spread.

Finston and Abrams outlined a scenario, based on the few facts available, of what could happen in the weeks and months following the accident in the vicinity of the nuclear reactor. Their predictions are based on, among other things, previous experience with radiation from the atomic bomb explosion in Hiroshima.

To follow their scenario requires learning a little about levels of radiation exposure. Abrams explained that scientists use three units for measuring tissues' radiation exposure, that are roughly similar: the "roentgen," the "rad," and the "rem." Radiation exposure is cumulative, Abrams explained.

Normal radiation levels are usually about 200 millirems each year for a person in the U.S., of which about 100 is naturally occurring radioactivity and 100 is manmade. A millirem is one thousandth of a rem. A common chest X-ray delivers about 20 millirems, he said. Up to about one-half a rem, or 500 millirems, is considered safe, Abrams added, although not desirable since any increase in exposure adds to a person's total cumulative radiation exposure.

A current generally accepted notion is that 200-400 rems is the "LD-50" (lethal dose for 50 percent of a population) for a single dose of radiation exposure, Abrams said. This means that 50 percent of a population of people exposed to this radiation level would die within 30 days, he said.

"An exposure of 25 rems or more is the level at which you start seeing blood count changes," said Finston, although the person most likely will not become ill.

Most scientific models suggest that highly lethal effects are limited to those who are within a 10-15 mile radius of a nuclear power plant accident, Finston said.

No one know what the actual exposure levels around the Soviet plant have been, but in a hypothetical situation, this is what would probably happen.

The first wave of deaths would occur among people exposed to thousands of rems, Abrams said. "These people would die within hours or days from central nervous system failure," he said. How radiation damages the brain is not fully understood, he said, but there is accumulation of fluids resulting in mental confusion, disorientation, and rapid death. There is no medical treatment possible for such victims, he added.

Those exposed to smaller, but still large, amounts of radiation such as 700-1,200 rads would die within days to weeks from gastrointestinal damage. External radiation and radioactive particles that are swallowed destroy the cells lining the GI tract, leading to nausea, vomiting and diarrhea as the GI tract can no longer absorb food. Medical treatment such as administration of fluids and intravenous nutrients could help but probably would not be able to prevent people from dying, Abrams said.

Those exposed to a dose below 700 rads could become sick or die within weeks due to damage to the bone marrow, which gives rise to all the body's red and white blood cells, Abrams said. As white blood cells are depleted, the person becomes highly susceptible to infection. As platelets diminish in number, hemorrhaging becomes a problem, he added, and with red cell loss, anemia may become profound.

Medical support in the form of antibiotics to fight infection, sterile conditions to minimize exposure to infection, or even bone marrow transplantation could help save people in this group, Abrams suggested. "There is a documented case of an individual exposed to 700 rads who was given a bone marrow transplant and survived," he noted.

Another danger for anyone who inhales any of the radioactive fallout is lung damage and lung cancer, Finston noted.

-more-

Any pregnant women, particularly those in the first trimester, are at particular risk for damage to the fetus, the two scientists agreed. Pregnant women who receive 100 rads or more will have a much greater risk of giving birth to a retarded or malformed child, Abrams said. Even a dose of 5 rads has the potential to harm unborn children, Finston noted.

Over days, weeks, and months as fallout settles to the ground, water in lakes and rivers and food crops such as vegetables and grains will be contaminated with radioactivity, Finston noted. People in the Ukraine and surrounding areas such as Poland should probably avoid eating crops or wash them thoroughly, he said. Milk becomes contaminated quickly because cows graze on large quantities of contaminated grass, he explained. Use of powdered milk would be advisable, he added.

Long term effects will be much more subtle, Finston and Abrams agreed, and are harder to predict. "There may be no dose of radiation below which you're guaranteed not to be harmed," he explained, "but your likelihood of damage goes down the lower your dose."

An increased incidence of leukemic cancer in the population near the accident site after about four or five years is predicted, Abrams said, judging from the Hiroshima experience. After about 10-12 years, there is likely to be an increase in the number of people who get lung, breast, thyroid, esophageal and bladder cancer, he added.

Daily doses of potassium iodide tablets might be recommended for those in the vicinity of the fallout, Finston said, who are likely to inhale or ingest radioactive iodine particles. The tablets protect against damage because if the thyroid gland absorbs enough normal iodine it can't take up any of the radioactive element. But there are some risks of hypersensitivity to the tablets, Finston noted, so this precaution will probably be limited to areas with significant fallout, he said. "Each country's public health agency should make a determination about this kind of prophylaxis," he said.

Abrams noted that there are some other simple precautions people in Europe or other areas can take if they are worried about fallout. "Stay indoors when the cloud passes over," he said, "or go in the basement. That alone can reduce your exposure tenfold." Abrams also said that even clothing alone could provide considerable protection to those outside the immediate area of the accident.

NEW TECHNIQUE ENHANCES USE OF MRI FOR SPINAL SCANS

STANFORD—

Magnetic Resonance Imaging (MRI) may become the standard method of diagnosing spinal problems, thanks to a new technique developed by researchers in diagnostic radiology at Stanford University School of Medicine.

MRI produces pictures of the human body and its organs that in many ways are superior to other imaging methods. It has been used for pictures of the spinal cord, but previous pictures sometimes lacked clarity.

The new technique provides much clearer pictures of the spine than previously possible through MRI scans and makes it feasible to use MRI routinely instead of the uncomfortable and sometimes risky procedure of myelography—which entails injection of dye through a needle and then taking X rays.

"I think we have discovered a very effective way of studying the spine and spinal cord," said Dr. Dieter Enzmann, associate professor of radiology and director of Stanford Radiology's magnetic resonance imaging program. "At this point, the technique that we have developed has the potential for replacing much of myelography."

The key to the new technique is the ability to adjust the MRI imaging sequence to match the patient's heart rate. That timing eliminates the interference that previously obscured many MRI images of the spine, especially in the neck.

MRI spinal scans are now performed regularly at Stanford's Advanced Imaging Center (Telephone: (415) 968-1750) and Enzmann predicts they will become common at other MRI centers throughout the nation. At present, the new technique is unique to Stanford radiology. It probably will be several months before other facilities develop the computer hardware and software necessary to perform spine scans in this way.

Stanford has not attempted to retain exclusive use of the new technique. In fact, researchers have made it readily available by presenting discussions on it at scientific meetings in recent months.

Dr. Jeremy Rubin, resident in radiology who was one of the three principal researchers on the project, was presented an award by the American Society of Neuroradiology in January for his role in the research. The award, the Cornelius G. Dyke Award, is for the best research performed by a young trainee or young faculty member in the field of neuroradiology.

EDITORS: Reporters and photographers are invited to attend the open house and tour the Stanford Alcohol and Drug Treatment Center on May 8. Anyone interested in a tour is requested to contact the Stanford University Medical Center Office of Communications, (415) 723-6911.

STANFORD ALCOHOL, DRUG TREATMENT CENTER TO OPEN

STANFORD—

The new Stanford Alcohol and Drug Treatment Center will open on Monday, May 12, offering inpatient and acute care programs for the first time in addition to outpatient treatment modeled on the long-established procedures of the Stanford Alcohol Clinic.

An open house will be held from noon to 7 p.m. Thursday, May 8, at the Hoover Pavilion, site of the new 14-bed inpatient unit. The center is a joint operation of the Stanford University Hospital and the Department of Psychiatry and Behavioral Sciences of the Stanford School of Medicine.

"It is very exciting to work on a comprehensive program that has inpatient and outpatient components and is tailored to individual patient needs," said Carole Price, hospital associate director who is the line administrator responsible for the center. "It is also competitively priced," she noted.

Adding the inpatient and acute care facilities means that the center will be prepared to treat "pretty much every problem that's alcohol and drug related," said Robert Matano, Ph.D., who is director of services.

Dr. Thomas A. Gonda, chairman of the Department of Psychiatry and Behavioral Sciences, made the same point. "We should be able to treat the more chronic, the more difficult cases much more effectively, because we're going to have a very wide spectrum of services," he said.

Matano pointed out that the center would be able to call upon "the richness of the resources that we have here at the University, the School of Medicine and the Hospital. We have the ability to bring together resources from medicine, from social science research, from family and educational studies."

Flexibility will be the key to treatment at the center, just as it has been with the outpatients helped at the alcohol clinic. Matano and Dr. William Hazle, medical director, emphasize that the length of inpatient hospitalization will be determined by individual patient needs—unlike the programs at some facilities that have requirements for 28- or 30-day stays.

Hazle explained that the center will rely more on shorter inpatient stays supplemented by short-term structured outpatient treatment and long-term therapy. Most patients will be involved with the center for about a year, he noted.

Matano said well-structured outpatient counseling is not only a more flexible method of treatment, but also is usually less expensive for the patient because the length of hospitalization is reduced.

Outpatient services will be in the site of the present alcohol clinic in the Psychiatry Building at the Stanford Medical Center. During the past nine years, the clinic has received national attention for its programs developed by Stephanie Brown, Ph.D.—particularly the treatment designed for the adult children of alcoholics.

Hazle said that "in some ways, this field (drug and alcohol treatment) is just getting started." He said the number of treatment centers in Santa Clara County has grown from two in 1979 to nine today, but not because of any increase in those addicted to drugs or alcohol. The numbers are approximately the same, he said, but there is a growing community awareness of the problem and the fact that it can be treated successfully.

Gonda also stressed the community need for such treatment, adding, "We're going to meet this need in the most modern way that we can, the most knowledgeable way that we can and the most cost-effective way that we can."

Price said the May 8 open house will feature brief introductory remarks by Gonda; Melvin Britton, president of the Hospital medical staff; and Michael Kidder, editor of the *Times Tribune*.4-29-86

BURNING CALORIES IS KEY TO DERIVING BENEFITS FROM EXERCISE, STANFORD RESEARCHER SAYS

STANFORD—

Just burning calories in exercise -not "super human efforts"- produces health benefits, according to William Haskell, Stanford associate professor of medicine and associate director of Stanford's Center for Research in Disease Prevention.

Most exercise regimes target particular heart rates or rates of oxygen consumption as goals, but "an increase in energy production" -burning calories- is the key stimulus promoting beneficial physiologic changes in the body, Haskell recently told the third annual symposium on Cardiovascular Nutrition. The symposium was cosponsored by the American Dietetic Association Practice Group of Sports and Cardiovascular Nutritionists (SCAN) and Stanford University Medical Center.

In adapting to the "stress" of exercise, beneficial physiologic changes occur in the body during and immediately following exercise, which leads to more efficient metabolism and reduced risk of developing coronary artery disease, as well as psychological benefits, Haskell said.

In his talk entitled "Is there an Exercise RDA (recommended daily allowance) for Good Health?," Haskell calculated the minimum energy expenditure needed to derive physiologic benefits from exercise based on numerous epidemiologic and physiologic studies.

Approximately four calories of energy for every kilogram of body weight (or 1.8 calories for every pound) should be expended at least every other day to get "relatively acute effects," he said.

For the average 165-pound man, this translates into approximately 30 to 40 minutes of "rigorous" exercise or 45 to 60 minutes of "moderate" exercise such as brisk walking, Haskell said. "Intensity and duration are always a trade off," he noted.

But significant health benefits can be achieved from low intensity exercise regimes focused on burning calories, Haskell said. Only slightly more benefits are derived from increasing the activity of an already active person, he said.

Very inactive persons benefit most from an increase in exercise because exercise rapidly reverses the detrimental health-related consequences of extreme inactivity, Haskell said.

In contrast to the large number of popular books and TV commercials promoting exercise and fitness, large numbers of people remain inactive, Haskell said. In fact, "national statistics show that 80 percent of men over 40 do not participate in any regular vigorous exercise," he said.

Because these people can't identify with television ads that feature very physically fit and slim people, such ads may serve as "a major deterrent to getting people to exercise," Haskell suggested. They "lead to the perception that to get any benefit you must achieve and look like that," Haskell said. Still, any regular activity produces substantial health-related benefits, he said.

Such benefits include an increased sensitivity to insulin, decreased levels of triglyceride in the blood, improved blood clotting mechanisms, and an increased ratio of HDL (good) cholesterol to LDL (bad) cholesterol, Haskell said.

He proposed that health professionals broaden their exercise prescriptions to include low intensity exercise regimes, focused on burning calories, so that larger numbers of people can benefit from exercise. "It is important to realize that there is a data base that says moderate exercise intensities are of good use," he said.

ETHICS PLAY AN EXPANDING ROLE IN MEDICINE

STANFORD—

Physicians and other health care professionals—buoyed by recent national policy statements and court rulings—are becoming more sophisticated and confident in dealing with ethical issues in medicine, said a Stanford University Medical Center expert.

Yet dealing with the costs and benefits of medical treatment, or who's involved in determining if treatment should be initiated and to what extent it should be carried out, or even the very questions of life and death, is "never going to get any simpler," said Dr. Ernle Young, director of the chaplaincy service.

Ethical issues will remain an important aspect of medicine, he explained in a recent interview, because of the growing number of people involved with an individual's care as well as new issues concerning medicine and health care delivery that society has to answer.

The medical profession received a shot of encouragment last month when the American Medical Association determined that it is appropriate for physicians to withdraw life-supporting artificial feeding systems from hopelessly comatose patients, explained Dr. Thomas Raffin, assistant chief of medicine. And recent court rulings upholding decisions to withdraw life support systems have enforced the individual's right of self-determination.

But at the same time, the Reagan administration has stepped up its lobbying efforts to reinstate the Baby Doe rule, struck down in 1984 by an Appeals Court. The rule provides for government "squads" to ensure that hospitals provide the same care to handicapped infants as to non-handicapped babies. And record-breaking malpractice suits continue to drive physicians' insurance premiums beyond reasonable limits. As a result, some physicians, such as obstetricians, are being forced out of practice.

In the midst of the activity, medical centers are establishing mechanisms to help guide the decisions of physicians, nurses, patients and families.

At Stanford, a medical center-wide ethics committee sets general policy and reviews cases on a retrospective basis. It includes not only physicians, but nurses, medical students, a chaplain, economists, lawyers, social workers, sociologists and a philosopher as well. Since its formation, members have reviewed issues such as withdrawing life support, 'do not resuscitate' codes, informed consent, animals in research, severely impaired newborns and economics.

Meanwhile, a hospital-based committee provides a panel of ethical experts for individuals to consult about ongoing cases. Patients in the intensive care unit (ICU) or neonatal ICU are most often the ones to pose dilemmas, said Young, who teaches medical ethics as well.

The most difficult decisions arise in the ICU when a patient has extensive but not complete brain damage, he elaborated. In the neonatal ICU difficult decisions arise when parents of a severely impaired newborn want treatment stopped prematurely, or want it continued after there is no hope. "Decisions in all these cases are legally risky, but we have to consider the ethical obligations."

4-28-86

The other principal researchers were Enzmann and Dr. Allan Wright, a fellow in cardiovascular radiology.

The concept behind MRI is that the body's nuclei can act as tiny magnets that can be manipulated by powerful magnets to give off signals. Those signals are interpreted by a computer to create images that give precise details of many parts of the body.

An MRI scan is simple and painless for the patient, requiring only that he or she lie inside a large, doughnut-shaped magnet for approximately 45 to 60 minutes. There are no known side effects and there is no exposure to radiation.

By contrast, myelography is what physicians call "invasive." It involves a puncture of the lumbar area of the spine and the injection of dye to outline the spinal cord and nerve roots. The patient must be placed in sometimes uncomfortable positions while X rays are taken of the spine.

Enzmann said there is "some risk" from the procedure and "it's often uncomfortable and has at times unpleasant side effects, either from the contrast medium that's used or just from simply having had a lumbar puncture."

MRI has been used for spinal scans, but, Enzmann said, "there were certain limitations where at times you would still fall back on the myelogram to answer some questions. At this point, there is much less reliance on the myelogram."

He said the new technique involved a lot of trial-and-error research. "We saw that we were getting artifacts on our spine scans and slowly through the process of investigation into what caused those artifacts we realized that if we timed our data acquisition with the cardiac cycle and kept that constant we could eliminate the artifacts and greatly improve the image quality."

The MRI scans now produced, he said, are for the most part equivalent to myelograms and at times superior, "and there's an advantage in comfort and less risk."

The cost of a myelogram ranges from $525 to $900 and that of an MRI scan from $600 to $800.

Stanford radiologists will hold a seminar on the new technique from 8:30 a.m. to 11:30 a.m. Saturday, May 17, in Room M-108 of the School of Medicine. Clinicians and any other interested persons are invited.

Some basic changes in medical practice have evolved over the last decade or so that influence the guidance that ethics committee members provide, said Raffin, who is also associate director of the ICUs. Increasingly sophisticated technology has enabled physicians to develop such procedures as renal dialysis and organ transplantation. They have also been able to nurture increasingly premature babies along to the point where their tiny bodies can provide the necessary elements for life. The establishment of ICUs has given physicians the ability to care for more acutely ill patients. Yet these advances carry with them a number of ethical questions, not the least of which are quality of life and cost.

Consider the case of an older man who, after two failed kidney transplants and a lifelong dependency on daily dialysis, decides he'd like to stop treatment and die. Should he be forced to live a life he can no longer bear? And who will pay for his continued dialysis treatment, and perhaps another transplant? Treatment for him and other Americans in similar positions is already costing Medicare an estimated $2.5 billion annually, said Dr. Carl Grumet, associate professor of pathology.

The issue of cost is permeating medical practice like a deadly cancer, Raffin said, turning what may at one time have been relatively straightforward decisions into ethical dilemmas that may include considerations such as whether long term benefits of any given treatment are worth the cost, and how to allocate increasingly limited health care resources.

"The traditional laissez faire-type of solo medical practice has evolved into health maintenance organizations and other large group practices," he observed. "Americans are now facing the concept of limited health care resources. Over the next decade or two, all Americans may not be able to have access to the most expensive, high-tech types of medical care that can be delivered."

If a terminally ill patient who would die in a couple of days wanted to be put on life support in an ICU, for example, he might not be allowed to because the costs would outweigh the benefits, Raffin explained.

"We've got to be fair in the allocation of scarce resources," Young added. "We've got to consider whether we can have what we want in the context of what others may want or need."

Justice is one principle Young and others use in guiding the decisions of physicians, patients and families. He also upholds the principle of autonomy; if at all possible patients should be able to choose their medical care—and the consequences—for themselves.

The Durable Power of Attorney for Health Care, in which individuals can describe what they would like to be done if they cannot speak for themselves, is now legally binding. *The Living Will* and *California Natural Death Act* are also helpful in determining future treatments.Individuals should fill them out when they are healthy, Raffin said. They are available through the hospital's department of patient and community relations, (415) 723-7176.

The most important guiding principle is one that states that the medical profession shall "do no harm," Young said. "If treatment will inflict more harm than good, it is not the optimal choice."

Malpractice suits and the growing involvement of lawyers with medicine have also had their effects, Raffin said. On one hand physicians are being told to cut back to reduce cost, yet on the other hand they are held liable for every possible outcome. "Physicians are practicing defensive medicine," he continued. "They're simply scared of being sued."

Key to the changes in medical practice, Raffin said, is the fact that consumers are much more informed about their health care. "The physician-patient relationship has changed dramatically over the last few decades. It used to be 'do whatever you think is best, doc.' Now, physicians tell patients all the possible options and jointly decide which to pursue."

This change has taken place, in part, because of an increased interest in health care by mass media, which has resulted in a better informed public, he said. Members of Stanford's ethics committees favor this trend. "People are worried about what will happen to them in the future," Raffin commented. "We're making an overall effort to bring these types of issues to the medical community and the public."

NEW HIGH-TECH WAY OF ANALYZING ELECTRICAL ACTIVITY PROVIDES CLEARER PICTURE OF BRAIN'S FUNCTIONS

STANFORD—

A new computerized method of analyzing the brain's electrical activity may provide physicians with a much clearer picture of how the brain functions and how it is affected by various diseases.

Using the new technique, called computer-analyzed EEG, physicians can create a rainbow-colored picture of the brain on a computer screen. Each hue represents a level of electrical activity. The method is totally noninvasive, yet it offers instantaneous information about brain function in a way that easily enables physicians to detect unusual patterns of activity or localized areas of abnormality.

The technique is also much more precise that other ways of reading EEGs, said Dr. Glen Elliott, a research physician in Stanford medical school's psychiatry and behavioral sciences department. These qualities may lead to it replacing the more standard techniques in many areas of medicine.

For example, neurologists are beginning to use it to diagnose a specific type of epilepsy that affects its victims by causing personality changes rather than seizures.

Some anesthesiologists use the technique to more effectively monitor the brain function of patients under anesthesia.

And psychiatrists may be able to gain insights on diseases such as autism, depression and schizophrenia, which may help them develop more effective therapies.

"We're excited about being able to detect consistencies in abnormalities of electrical activity for different diagnostic groups," Elliott said.

The technique is based on something called fourier analysis, developed years ago by a mathematician for use in mathematics and physics. It essentially breaks down the signals created by the brain's electrical activity into component parts. The computer then reconstructs them in a much simpler way and displays the results as colored maps of the brain surface. A table of all the colors of the spectrum serves as the guide to be able to read the levels of activity. The patient simply puts on a special cap that contains all the electrodes and is hooked up to the computer.

4-28-86

-more-

2-2-2

The machine is still fairly rare and is expensive, Elliott said. But he sees it gaining a prominent place in medicine. "There are no dramatic breakthroughs yet, but it gives us a different way of studying people with disorders in the brain."

An EEG, or electroencephalogram, produces a graph in which each line represents the electrical activity measured by individual electrodes attached to the skull. The ability to read the graphs takes considerable experience and expertise, Elliott explained. If the electrical activity in one area of the brain looks abnormal, he added, it can be difficult to determine if the abnormality stems from that area, or if it is simply spreading from another portion of the brain.

With the new technique, however, it is easily distinguishable to even an untrained observer how much electrical activity is produced throughout the brain. Physicians are able to pinpoint precisely if and where any abnormal activity is taking place, and how it dissipates to affect the rest of the brain.

"With an EEG there's always the possibility of missing something," Elliott said. "With this there's a sense of coherance. The computer can process information over time and space—something the human brain has trouble doing."

The computer-analyzed EEG can measure the brain's electrical activity over time, and it can detect changes much more subtle than those picked up by the standard EEG, he said.

It also shows how the brain processes information and can compare activity of the right side with the left side. If a patient is asked to solve math problems or speak, for example, the left side of the brain becomes more active, he explained. Yet if the patient is listening to music, it shows up on the right side of the brain.

"You can't do this type of comparison with an EEG," Elliott said.

WEIGHT LOSS PROGRAM DEVELOPING FOR PRESCHOOL YOUNGSTERS

STANFORD—

A research team is hoping to halt obesity before it becomes a lifelong problem by working with preschool youngsters and their families.

While obesity programs for adults and adolescents are common, the director of the new program believes this is the first time that a medical school-sponsored program has been introduced for preschool children.

"Obesity, particularly in children, produces both physical and psychological problems. Our objective is to modify a family's eating behavior and patterns of physical activity before the youngster is even objectively aware of his condition.

"By doing so, we may be able to alter the negative psychological consequences and medical risks of obesity," said Dr. Lawrence D. Hammer, director of the Stanford-Children's Ambulatory Care Center at Children's Hospital at Stanford.

Hammer said that obesity in young children is caused by many of the same forces which cause the condition in adults, including genetic predisposition and food intake greater than needed. "It just starts earlier in some people than in others," Hammer said. "And there appears to be a greater likelihood of longterm obesity in youngsters who start becoming overweight in the preschool years."

He noted that children in their early school years are o*h* teased and taunted by their peers for being overweight. This can cause permanent psychological problems, he said.

Also, weight loss is easier to accomplish in a young child than in an adult when food habits have been established, and when physiological factors make shedding weight more difficult, Hammer said.

For the current study, Hammer is looking for several youngsters in the 4 to 6 age range who are already at least 10 percent overweight without an underlying medical cause.

The project is part of ongoing research and there would be no charge for treatment during the study, Hammer said.

The youngsters would need to be accompanied by at least one parent on 10 weekly visits to CHAS starting May 12. Each visit would last about two hours, said Hammer, who is an assistant professor of pediatrics at Stanford.

"Proper diet is a family affair, and especially for a youngster, participation of all family members in supporting a change in eating habits is crucial," Hammer said.

The behavioral treatment program couples nutrition education with techniques designed to increase physical activity and promote healthy eating.

For further information, contact Hammer at (415) 327-4800, ext. 539. The project is funded by the multidisciplinary Stanford Center for the Study of Youth Development.

The Ambulatory Care Center also sponsors an obesity evaluation clinic and weight loss programs for elementary school age children and teenagers, he said.

FIRST LAZARD FACULTY SCHOLAR APPOINTED AT STANFORD MEDICAL SCHOOL

STANFORD—

Dr. Richard Roth, assistant professor of pharmacology, has been appointed the first Lazard Faculty Scholar at Stanford University School of Medicine, Dean David Korn has announced.

The Lazard Scholarship, established by Stanford alumnus Claude-Eric Lazard and his two sisters, provides $20,000 per year to a beginning assistant professor pursuing "exciting and promising research," Korn said. The award "permits us to reward brilliant young scientists on our junior faculty," Korn added.

Roth, who joined the Stanford faculty in 1984, was selected from among more than 50 applicants for the honor by a new Committee on Faculty Awards.

Roth's research centers on the action of insulin, one of the body's important hormones. He participated in the first successful attempts to clone the gene for the human insulin receptor, a protein involved in mediating insulin's actions on cells. He was also one of the first investigators to produce monoclonal antibodies to the human insulin receptor. These antibodies should aid research efforts aimed at understanding the hormone's actions throughout the body.

Roth, 35, received his Ph.D. from Brown University, went on to a postdoctoral fellowship at the University of California, Berkeley, and subsequently became a senior research investigator at Mt. Zion Hospital and Medical Center in San Francisco prior to his appointment at Stanford.

Lazard, a New York financial consultant, is a 1961 graduate of Stanford University who majored in economics. Through the years, he also has maintained a longstanding interest in medicine and biomedical research. In 1969, he established a fund to support research at Stanford Medical School in memory of his mother, Esther Ehrman Lazard.

This is the first year that the Lazard Scholarship has been awarded competitively. Terms of the fund stipulate that the same candidate cannot be appointed for more than three consecutive years.

STANFORD PATHOLOGIST RECEIVES WARNER LAMBERT/PARKE-DAVIS AWARD

STANFORD—

Dr. Gerald R. Crabtree, associate professor of pathology at Stanford University School of Medicine, has been named the recipient of this year's Warner Lambert/Parke-Davis Award.

The award is given annually by the American Association of Pathologists (AAP) to an experimental pathologist under 40 whose research has made a substantial contribution to pathology.

Crabtree received the award on April 14 during the AAP's annual meeting in St. Louis.

A graduate of West Liberty State College in West Virginia, Crabtree obtained his M.D. from Temple University Medical School in 1972.

After his residency at Dartmouth-Hitchcock Medical Center, he held research positions at Dartmouth Medical School and at the National Institutes of Health before joining the Stanford faculty in 1985.

His research focuses on the regulation and evolution of the genes for fibrinogen, a blood coagulation factor, and on control of the human interleukin-2 and interleukin-2 receptor genes and their relation to various types of cancers.

JAMES B. WYNGAARDEN: 'NO RECKLESS BUDGET SLASHING AT NIH'

—STANFORD

"The impression that the bottom is dropping out in the support of biomedical science is simply untrue," says the director of the National Institutes of Health (NIH).

"Things are going to be tighter, but the 1987 NIH budget represents a substantial commitment to biomedical research," Dr. James B. Wyngaarden said in an interview responding to questions from Stanford faculty.

Fifteen years ago the NIH was funding only about 10,500 research grants, he noted. In 1987 the number will be 18,000, compared with 18,649 this year.

The Gramm-Rudman-Hollings deficit reduction law, which exempts Social Security and defense, applies to all branches of the federal government. The law has imposed a cut of 4.3 percent or $236 million in this year's budget authority of the NIH, down from $5.5 billion to $5.13 billion.

"But there hasn't been reckless budget slashing," Wyngaarden insisted.

"What creates a lot of tension is that grants have doubled, but the number of applicants has tripled, and competition is intense," he said. "We haven't been able to develop resources to parallel the increase in the number of scientists and fundable ideas."

Wyngaarden said the NIH has been subject to the same economic unpredictabilities as the nation as a whole.

"But my sense is the Congress won't let that deficit have a destructive effect on the country's scientific effort," he added.

Wyngaarden was in Palo Alto last week to talk about the "outlook for academic research" at the annual meeting of the Pacific Division of the American Association for the Advancement of Science.

The 4.3 percent cut this year, Wyngaarden said, will apply to the budget of each institute of NIH. Health research, education and training, and NIH intramural programs will be affected evenly. Programs defined by dollar value, such as AIDS research, will be reduced similarly.

The administration's 1987 budget also has proposed an additional $77 million cut in NIH's 1986 congressionally approved budget. The $77 million could not be spent until the reduction request was approved within 45 days by the Congress.

But the Congress has not acted on the request, and Wyngaarden indicated that eventually the $77 million will come back to the NIH.

4-22-86

-more-

Gramm-Rudman cuts will not affect the number of new and competing grants authorized this year, which is 6,100, Wyngaarden said. But they will be funded at a level 7 or 8 percent lower than planned. "With the reductions coming so late in the year, the impact on the budget is greater than the actual 4.3 percent," he noted.

Wyngaarden admitted that 1987 will be complicated by additional savings proposed in the president's budget. One modifies the indirect cost reimbursement to institutions, resulting in savings of about $85 million. The other will transfer about $143 million in AIDS research funds from the NIH to the budget of the assistant secretary of health.

Under the 18,000 research grant ceiling, new and competitive grants will be reduced from 6,100 to 5,140 in 1987.

"Because of the budget cuts and the average cost of a grant rising about 10 percent a year, the NIH will not have the money to support 5,140 new grants at full cost," Wyngaarden said. "If we fund them at lower levels, we'll be changing the scope of projects, creating difficulties for the scientists involved.

"For these reasons, I favor funding fewer new projects but higher quality work and funding it adequately."

Similarly, the biomedical research support program will be eliminated, resulting in a $63 million cut. These, coupled with the indirect cost savings if lowered as planned, would reduce the 1987 NIH budget to about $4.9 billion compared with $5.13 billion in 1986.

Wyngaarden acknowledged that the elimination of biomedical research support grants which have provided discretionary funds to medical school deans "doesn't obviously strengthen the universities."

He declined to comment on the controversy concerning another contested issue — administrative indirect costs on grants. The Office of Management and the Budget has proposed caps at rates of 26 percent this year and 20 percent next year. These, the universities say, would increase their costs of doing government-sponsored research.

"That's a major policy issue," Wyngaarden said. "It would not be appropriate for me to comment."

But in an interview in the May 1985 issue of the *Newsletter of the Federation of American Societies for Experimental Biology*, the NIH director did say that academic institutions are under "enormous" stress.

"The health of higher education institutions in this country is absolutely critical," he was quoted as saying. "We're utterly dependent on them to meet the mission of NIH and we're one component of all the things higher educational institutions do for this mission.

"So, the indirect cost issue has to be considered in the context of a near crisis situation for financing of higher educational institutions."

Wyngaarden said the 1987 budget has given him an opportunity to set a realistic target for NIH and the Congress with regard to new and competing awards and number of trainees.

He said he favors giving the highest priority to investigator-initiated grants. "That's the mechanism that most effectively captures the creative power of the scientist," he said. "Most of the important breakthroughs have come from this type of support."

-more-

Next on the priority list is training. "We have to insure there's a continuing supply of highly competent scientists coming into the system," he said.

The NIH presently supports about 10,000 students, more than a third of whom are in graduate training. The figure will drop to 9,200 next year unless the Congress changes it.

A report by the National Academy of Sciences has called for about 10,400 trainees to be funded in any budget year. But a serious problem facing NIH is high tuition costs, Wyngaarden said. "The budget does not permit us to continue to support the number recommended by the academy and pay full tuition." The issue is being addressed in consultations with the universities.

Wyngaarden noted the percentage of the NIH funds that support basic biomedical research today is about 63 percent compared with 30 percent 15 years ago.

"There's no question the administration and the Congress are solidly committed to support of biomedical sciences and health-related research," he said.

Wyngaarden conceded that one problem the NIH budget doesn't address is equipment. The fraction for equipment has declined to about 2.9 percent of the average project award, and 4 to 4.5 percent of the total NIH budget, including funding of large instrument programs.

While allocations for instruments of more than $100,000 that are shared by two or more grantees are on target, there's a serious shortfall in small instruments costing between $5,000 and $60,000, he said.

"The shortfall is greater in state-supported institutions," he said. "Many projects cannot be attempted because of the lack of instrumentation. Our funding has fallen below the critical area and we need to address it."

Tighter budgets are also forcing the NIH to cut agency red tape, Wyngaarden said.

The remedies? A limit on the length of grant applications. "Scientists now have to write small books when they apply," Wyngaarden said. "It borders on the absurd."

He said NIH will introduce two new programs of longer awards. For the first time, junior scientists applying for certain kinds of grants will be given four- to five-year awards — this to give them adequate time for creative research.

"For highly productive career scientists, we're proposing to make seven- to 10-year awards," he said.

These will be granted in two stages: an initial five-year award, with an extension of two to five additional years based on a progress report.

EDITORS: Text accompanies story.

This is the edited text of an interview with Dr. James B. Wyngaarden, director of the National Institutes of Health since 1982. Dr. Wyngaarden was in Palo Alto last week to address the first annual Pacific Division meeting of the American Association for the Advancement of Science on academic research and the 1987 federal budget. The questions posed to Dr. Wyngaarden were chosen to reflect faculty concerns at the Stanford University Medical Center

Q: News reports about the effects of the Gramm-Rudman-Hollings deficit-reduction law on the budget of the National Institutes of Health (NIH) vary, depending on the publication. Can you set the record straight?

A: Let me begin with the NIH budget for fiscal 1986. The original congressionally approved budget was $5.5 billion. Gramm-Rudman imposed a cut of 4.3 percent. This means a reduction of $236 million in budget authority.

Q: What immediate effect does this have on NIH programs and grantees?

A: The net effect will be a cut in the funds actually planned to be spent by the NIH for the remainder of this year. Some researchers who have yet not received an NIH grant but expected to get one sometime next fall may not get it.

Q: Will these reductions be across the board?

A: Yes. The 4.3 percent cut will apply to the budgets of each institute. Health research, education and training, and NIH intramural programs will be affected evenly.

Programs defined by dollar value in the appropriation bill will be reduced similarly. An example is AIDS research.

Q: As I understand it, the administration's 1987 budget has proposed an additional $77 million cut in your 1986 congressionally approved budget. Where will this money come from?

A: Most was to come out of research project grants. The proposal had to be approved by the Congress within 45 days. The Congress has not acted and eventually this money will come back to the NIH. As a result we hope to be able to give many applicants a precise answer on the status of their grant proposals.

Q: The 1986 NIH appropriation had set the number of new and competing grants to 6,100. Will Gramm-Rudman affect this number?

A: The number of 6,100 for fiscal 1986 will remain the same. But these grants will be funded at a level 7 or 8 percent lower than anticipated. With the reductions coming so late in the year, the impact on the budget in certain instances is greater than the actual 4.3 percent.

Q: What will the 1987 NIH budget look like?

A: The 1987 picture is complicated by additional savings proposed in the president's budget. One modifies the indirect cost reimbursement to institutions, resulting in savings of about $85 million. The other will transfer about $143 million of AIDS research funds from the NIH to the budget of the assistant secretary of health.

Similarly, the biomedical research support program will be eliminated, resulting in a $63 million cut. These, coupled with the indirect-cost savings if lowered as planned, would reduce the 1987 NIH budget to about $4.9 billion compared to this year's $5.13 billion.

Q: Reports have suggested that the federal government does not now support the full costs of university research. Yet you're eliminating general-purpose support grants. Aren't you making things even more difficult for medical schools?

A: Biomedical research support grants have provided minimally restricted funds for the universities over the years. Their elimination doesn't obviously strengthen the universities. It would have some impact. But the 1987 budget has also features designed to give top priority to investigator-initiated research grants, including a commitment to fund 18,000 research projects, which is a new expression of stabilization. I consider this a positive development.

Q: What do you mean by "stabilization"?

A: Stabilization has given me an opportunity to set a realistic target for NIH and the Congress with regard to new and competing awards and number of trainees. I realize the issue has caused concern in the scientific community, but from where I stand it has given the Congress the leverage to construct the NIH budget in a manner that allows more money for investigator-initiated research project grants and basic research.

Q: What are we talking about in terms of specific figures?

A: The percentage of the NIH budget that supports basic biomedical research is about 62 percent. It was around 30 percent 15 years ago. Each year during this period the Congress had added funds to the budget to bring us to the present level.

Q: But with respect to the 1987 budget, isn't the total number of NIH grants being reduced?

A: The 1987 budget has proposed a ceiling of 18,000 research grants starting in 1987. The number of new and competitive grants will be determined by the difference between continuation awards and 18,000.

Under this limit, new and competitive grants will be cut from 6,100 to 5,140. Because of the cuts and the average cost of a grant rising about 10 percent a year, which is higher than the rate of inflation, the NIH will not have the money to support 5,140 new grants at full cost. If we fund them at lower levels, we'll be changing the scope and character of projects, creating difficulties for the scientists involved.

Q: What are some of these difficulties and what do you propose to do?

A: When you reduce the scope of a project, initially that small cut will come out of supplies and other expendables. Seventy percent of the expense in a grant is personnel. About 4 percent is in equipment. You trim the supplies and it doesn't take long to realize you're not doing the job. If you, on the other hand, protect the supply category, the obvious alternative is to cut personnel. For these reasons I favor funding fewer projects but higher quality work and funding it adequately.

Q: From a personal standpoint how do you feel about these cuts, the future of NIH, and our national commitment to biomedical research?

A: I'm optimistic about it. Things are going to be tighter, but there's no question the administration is solidly committed to continued support of biomedical research, including basic research specifically. The Congress, both houses and members of both parties, view biomedical science and health-related research as a very high national priority.

Even the Heritage Foundation, which normally doesn't favor government expenditures for many things, feels the NIH fully warrants substantial government support for its value to health, for its contributions to development of new industries and the nation's economic well-being.

Now having said that, I don't think the NIH will be exempted from present fiscal constraints. We're not going to be treated in the same category as national defense or Social Security. There's no realistic possibility of that happening. But what the Congress does to the 1987 budget is an important bellwether.

-over-

A: We've heard this concern raised often. I'd like to make two points. When you look at the NIH budget between 1977 and 1985, the intramural programs grew 111 percent, the extramural 114 percent. There's some fluctuation between the two in given years, but overall their growth has been symmetrical.

My other point is that intramural programs have no citizen advocacy. We have to protect NIH intramural activities in our budget formulation. When the proposed budget is presented by the president in late January or early February before public hearings actually begin, the NIH intramural programs seem to have a higher priority.

But those who think so overlook the dynamics of the appropriations process. When reinforced by witnesses from professional societies, special disease agencies, and families of victims of disease, the Congress adds funds to the NIH budget each year. These go disproportionately to the extramural program, and the outcome is symmetrical growth.

Q: Many scientists think that NIH's intramural programs are generally first-class and match those one finds in academic centers. But there are also weak programs. How do you decide which intramural programs get funded and which do not?

A: We have an active review process by outside advisers for each institute. They review the work of laboratories and individual scientists every three years and recommend the level at which they should be supported. On that basis, some programs are expanded, others constricted.

Some university scientists would like to see prospective peer review applied to the budgets of NIH intramural programs, which is what they have to go through themselves. I'd suggest an alternative. Rather than saddle the intramural programs with all the encumbrances of the extramural review process, we should work on reducing the red tape for the extramural scientists. As I pointed out, we're trying to do that.

Q: In the United States there's a growing consumer movement demanding cost-effective and safer medical and surgical treatments. The safety and efficacy of many procedures can be established through careful clinical trials. Do you think the NIH has a responsibility to support clinical trials and if so, what will happen to those after Gramm-Rudman?

A: We have a responsibility in this area. We have supported clinical trials and they're a visible part of what we do. When the budgets are constrained, however, we can only fund a smaller number. The Congress asks many details about clinical trials. At the last appropriations hearing I cited 12 examples that had led to annual reductions in health care expenditures totaling $2.5 billion.

Q: Can you cite specific examples?

A: One was a clinical trial of the use of a drug called indomethacine for closure of patent ductus arteriosus in children. This condition occurs when the blood vessel that links the pulmonary artery and aorta before birth fails to close properly after birth. The leakage puts an additional strain on the baby's heart. The ductus or vessel can be severed and closed off in a surgical procedure. But there's now a less expensive approach, thanks to the work of Abraham Rudolph, professor of pediatrics at UC-San Francisco.

Rudolph had studied the physiological mechanism of the maintenance of the patent ductus in fetal lambs. He found that prostaglandins present in the ductal wall maintained the prenatal patency of the ductus of fetal sheep and that inhibitors of prostaglandin synthesis such as indomethacine caused constriction of the vessel. After the animal observations, studies with indomethacine were carried out in premature babies with patent ductus arteriosus. Such treatment for several days was followed by closure of the vessel in the majority of infants.

Subsequent clinical trials, supported by the National Heart, Lung and Blood Institute, found that 85 percent of children with that condition could be managed medically. The clinical trial cost $1 million, the cost of the medical treatment is about $40 per patient. The total savings of that innovation to the country is on the order of $200 million a year.

Another multicenter study, which sounds rather trivial, had to do with the criteria for tonsillectomy. The removal of tonsils had been performed almost ritually by physicians for decades. The study established new criteria leading to a remarkable decline in tonsillectomies nationwide. The Institute of Child Health and Human Development estimates the annual cost savings on the order of $800 million.

Q: What is your position on the pork-barrel projects approved by the Congress last year? The question refers to funding facilities for specific institutions bypassing the normal peer review process.

A: We don't have any official position on this issue. My personal view is that we'd like to see as many of these projects as possible subjected to peer-review. But the number of instances in which this review has been bypassed is not large.

Q: Various reports have suggested that as a nation we have not provided the necessary investments required to maintain university laboratories and equipment up-to-date. Do you plan to address this issue?

A: We're very concerned about it. The fraction of the NIH budget for equipment in individual grants has declined over time. Now it's about 2.9 percent of the average project award, and 4 to 4.5 percent of the total NIH budget, including large instrument funding programs. The NIH studied the shortfall in availability of large instruments that can be shared among two or more grantees. The shortfall was estimated at about $100 million per year. We've set a target of $20 million a year to alleviate that, and we're exceeding that amount every year. But we don't think the shortfall will be made up in five years, even though we're on target with respect to instruments costing $100,000 to $200,000.

Another study has indicated a very serious shortfall in small instruments costing between $5,000 and $60,000. The shortfall is greater in state-supported institutions, with a number of chairmen reporting that many research projects cannot be attempted because of the lack of instrumentation.

We've discussed this issue with the institute directors' advisory committee. Our sense is that our funding has fallen below the critical level and we need to address it.

Q: How can scientists help you in your efforts?

A: There's no country in the world that prepares its budgets for science the way ours does. It's important that our scientists understand the process and its politics. We at the NIH propose, defend, and appeal budget decisions, but there comes the time when the president's budget is formally presented each year. From that moment on I'm obliged to defend those decisions.

The special interest groups make their case to the Congress. The scientific community has the opportunity and obligation to make its case. But the effective way is to make it on altruistic grounds. It's not appropriate for scientists to make their case on the basis of personal pain. There's a lot of pain in the country. Our farmers are in trouble, small business people are suffering. Right now even the oil producers are in trouble. The idea that all scientists should be kept working, which is often the case made, I think damages the effort.

Q: In your opinion how does science fare in terms of public support?

STANFORD HOSPITAL NAMES DIRECTOR OF NURSING

STANFORD—

Malinda Mitchell has been appointed associate hospital director and director of nursing, Executive Vice President William Arnold announced.

Mitchell had been performing both jobs on an acting basis since Oct. 1. She replaces Duane Walker, who resigned to become vice president of Queens Medical Center in Honolulu.

"Our nationwide search has ended," Arnold told members of the hospital executive committee. "Malinda Mitchell was clearly the best candidate for the position."

Mitchell has been sitting on the executive committee since her interim appointment began. She will continue as a member of the committee.

She has been a hospital employee since August 1975, starting as a clinical nursing coordinator. In January 1979, she was appointed assistant director of Nursing with responsibility for all surgery areas. She was named associate director of nursing in May 1982.

Mitchell received her training as a registered nurse at the University of Illinois and earned a master's degree in her field at Indiana University. She recently received an M.S. in management as a Sloan Fellow at Stanford's Graduate School of Business.

STANFORD HOSPITAL HIRING NURSES TO ACCOMODATE INCREASED PATIENT CENSUS

STANFORD—

Take down the vacancy signs and call out the recruiters. Stanford University Hospital's intensive care units (ICUs) are overflowing and more nurses are needed to care for the increased number of patients.

The department of nursing services is hiring "experienced ICU nurses" as fast as it can, said Judy Lanigan, assistant director in charge of staffing. It had about 30 openings; about 20 of those have yet to be filled.

"Nobody knows why this is happening," said Malinda Mitchell, director of nursing service. But for about six weeks now, the number of patients in the pediatric and adult ICUs have burst not only beyond the depressed hospital census, but past the budgeted census as well.

Possible explanations include an increase in cardiovascular surgery patients and an increase in heart transplant patients, Mitchell said. Also, since the hospital was designated one of three trauma centers for Santa Clara County, there has been a slight increase of trauma patients who are admitted to the hospital. But none of these reasons account for all of the current situation, she noted.

Other peninsula hospitals are experiencing similar overloads, Mitchell said.

During the last two months, the ICUs have been running about 18 percent or more above the number of patients expected, Lanigan said. Nurse staffing is based on the number of patients, especially in the ICUs where in most cases one or two patients are cared for by one nurse on a 24-hour basis, she explained. Nurses have been working overtime and relief nurses have been scheduled to fill in the gap, but such measures only work temporarily.

"After a week or two of working overtime, you begin to get pretty tired," Mitchell said.

The nursing shortage comes as a suprise on the tails of the hospital's "downsizing" last month in response to fewer patients and shorter hospital stays by patients. No nurses were laid off during the downsizing, Mitchell said, but budgeted nursing positions were eliminated in anticipation of decreased staffing needs.

"We had stopped our recruitment efforts, and had put a hold on all our applicants," Lanigan said. But no more. "If the census continues to stay high, we'll need another 20 nurses in addition to those we need to hire now."

KORN REAPPOINTED CHAIRMAN OF CANCER ADVISORY BOARD

STANFORD—

Dr. David Korn, vice president and dean of the Stanford University School of Medicine, has been reappointed by President Reagan as chairman of the National Cancer Advisory Board (NCAB).

Korn was appointed in 1984 to a six-year term as a member of the board, then named to a two-year term as chairman. His second term as chairman runs through March 8, 1988, and his board term expires March 8, 1990.

The NCAB is an advisory panel to the director of the National Cancer Institute (NCI). Eighteen members are appointed by the president and there are also 11 ex-officio members from various government offices.

Board members advise the NCI director on activities of the National Cancer Program, the United States' comprehensive effort aimed at fighting cancer. They also review applications for grants-in-aid relating to cancer research.

The board meets four times a year at the National Institutes of Health in Bethesda, Md.

Korn previously served as an adviser on cancer to the federal government as a member of the Board of Scientific Counselors, Division of Cancer Biology and Diagnosis, National Cancer Institute. He was a member of the board from 1977 to 1982 and chairman from 1980 to 1982.

His own research is on enzymes that synthesize DNA and are involved in DNA replication of higher organisms.

Korn received both his undergraduate and medical degrees from Harvard University. He has been on the Stanford Medical School faculty since 1968, when he was named chairman of the Department of Pathology. He became dean of the School of Medicine in 1984 and added the title of vice president in an organizational change that took place last January.

JAMES B. WYNGAARDEN: 'NO RECKLESS BUDGET SLASHING AT NIH'

—STANFORD

"The impression that the bottom is dropping out in the support of biomedical science is simply untrue," says the director of the National Institutes of Health (NIH).

"Things are going to be tighter, but the 1987 NIH budget represents a substantial commitment to biomedical research," Dr. James B. Wyngaarden said in an interview responding to questions from Stanford faculty.

Fifteen years ago the NIH was funding only about 10,500 research grants, he noted. In 1987 the number will be 18,000, compared with 18,649 this year.

The Gramm-Rudman-Hollings deficit reduction law, which exempts Social Security and defense, applies to all branches of the federal government. The law has imposed a cut of 4.3 percent or $236 million in this year's budget authority of the NIH, down from $5.5 billion to $5.13 billion.

"But there hasn't been reckless budget slashing," Wyngaarden insisted.

"What creates a lot of tension is that grants have doubled, but the number of applicants has tripled, and competition is intense," he said. "We haven't been able to develop resources to parallel the increase in the number of scientists and fundable ideas."

Wyngaarden said the NIH has been subject to the same economic unpredictabilities as the nation as a whole.

"But my sense is the Congress won't let that deficit have a destructive effect on the country's scientific effort," he added.

Wyngaarden was in Palo Alto last week to talk about the "outlook for academic research" at the annual meeting of the Pacific Division of the American Association for the Advancement of Science.

The 4.3 percent cut this year, Wyngaarden said, will apply to the budget of each institute of NIH. Health research, education and training, and NIH intramural programs will be affected evenly. Programs defined by dollar value, such as AIDS research, will be reduced similarly.

The administration's 1987 budget also has proposed an additional $77 million cut in NIH's 1986 congressionally approved budget. The $77 million could not be spent until the reduction request was approved within 45 days by the Congress.

But the Congress has not acted on the request, and Wyngaarden indicated that eventually the $77 million will come back to the NIH.

4-22-86

-more-

Gramm-Rudman cuts will not affect the number of new and competing grants authorized this year, which is 6,100, Wyngaarden said. But they will be funded at a level 7 or 8 percent lower than planned. "With the reductions coming so late in the year, the impact on the budget is greater than the actual 4.3 percent," he noted.

Wyngaarden admitted that 1987 will be complic..ted by additional savings proposed in the president's budget. One modifies the indirect cost reimbursement to institutions, resulting in savings of about $85 million. The other will transfer about $143 million in AIDS research funds from the NIH to the budget of the assistant secretary of health.

Under the 18,000 research grant ceiling, new and competitive grants will be reduced from 6,100 to 5,140 in 1987.

"Because of the budget cuts and the average cost of a grant rising about 10 percent a year, the NIH will not have the money to support 5,140 new grants at full cost," Wyngaarden said. "If we fund them at lower levels, we'll be changing the scope of projects, creating difficulties for the scientists involved.

"For these reasons, I favor funding fewer new projects but higher quality work and funding it adequately."

Similarly, the biomedical research support program will be eliminated, resulting in a $63 million cut. These, coupled with the indirect cost savings if lowered as planned, would reduce the 1987 NIH budget to about $4.9 billion compared with $5.13 billion in 1986.

Wyngaarden acknowledged that the elimination of biomedical research support grants which have provided discretionary funds to medical school deans "doesn't obviously strengthen the universities."

He declined to comment on the controversy concerning another contested issue — administrative indirect costs on grants. The Office of Management and the Budget has proposed caps at rates of 26 percent this year and 20 percent next year. These, the universities say, would increase their costs of doing government-sponsored research.

"That's a major policy issue," Wyngaarden said. "It would not be appropriate for me to comment."

But in an interview in the May 1985 issue of the *Newsletter of the Federation of American Societies for Experimental Biology*, the NIH director did say that academic institutions are under "enormous" stress.

"The health of higher education institutions in this country is absolutely critical," he was quoted as saying. "We're utterly dependent on them to meet the mission of NIH and we're one component of all the things higher educational institutions do for this mission.

"So, the indirect cost issue has to be considered in the context of a near crisis situation for financing of higher educational institutions."

Wyngaarden said the 1987 budget has given him an opportunity to set a realistic target for NIH and the Congress with regard to new and competing awards and number of trainees.

He said he favors giving the highest priority to investigator-initiated grants. "That's the mechanism that most effectively captures the creative power of the scientist," he said. "Most of the important breakthroughs have come from this type of support."

-more-

Next on the priority list is training. "We have to insure there's a continuing supply of highly competent scientists coming into the system," he said.

The NIH presently supports about 10,000 students, more than a third of whom are in graduate training. The figure will drop to 9,200 next year unless the Congress changes it.

A report by the National Academy of Sciences has called for about 10,400 trainees to be funded in any budget year. But a serious problem facing NIH is high tuition costs, Wyngaarden said. "The budget does not permit us to continue to support the number recommended by the academy and pay full tuition." The issue is being addressed in consultations with the universities.

Wyngaarden noted the percentage of the NIH funds that support basic biomedical research today is about 63 percent compared with 30 percent 15 years ago.

"There's no question the administration and the Congress are solidly committed to support of biomedical sciences and health-related research," he said.

Wyngaarden conceded that one problem the NIH budget doesn't address is equipment. The fraction for equipment has declined to about 2.9 percent of the average project award, and 4 to 4.5 percent of the total NIH budget, including funding of large instrument programs.

While allocations for instruments of more than $100,000 that are shared by two or more grantees are on target, there's a serious shortfall in small instruments costing between $5,000 and $60,000, he said.

"The shortfall is greater in state-supported institutions," he said. "Many projects cannot be attempted because of the lack of instrumentation. Our funding has fallen below the critical area and we need to address it."

Tighter budgets are also forcing the NIH to cut agency red tape, Wyngaarden said.

The remedies? A limit on the length of grant applications. "Scientists now have to write small books when they apply," Wyngaarden said. "It borders on the absurd."

He said NIH will introduce two new programs of longer awards. For the first time, junior scientists applying for certain kinds of grants will be given four- to five-year awards — this to give them adequate time for creative research.

"For highly productive career scientists, we're proposing to make seven- to 10-year awards," he said.

These will be granted in two stages: an initial five-year award, with an extension of two to five additional years based on a progress report.

As a result we hope to be able to give many applicants a precise answer on the status of their grant proposals.

Q: The 1986 NIH appropriation had set the number of new and competing grants to 6,100. Will Gramm-Rudman affect this number?

A: The number of 6,100 for fiscal 1986 will remain the same. But these grants will be funded at a level 7 or 8 percent lower than anticipated. With the reductions coming so late in the year, the impact on the budget in certain instances is greater than the actual 4.3 percent.

Q: What will the 1987 NIH budget look like?

A: The 1987 picture is complicated by additional savings proposed in the president's budget. One modifies the indirect cost reimbursement to institutions, resulting in savings of about $85 million. The other will transfer about $143 million of AIDS research funds from the NIH to the budget of the assistant secretary of health.

Similarly, the biomedical research support program will be eliminated, resulting in a $63 million cut. These, coupled with the indirect-cost savings if lowered as planned, would reduce the 1987 NIH budget to about $4.9 billion compared to this year's $5.13 billion.

Q: Reports have suggested that the federal government does not now support the full costs of university research. Yet you're eliminating general-purpose support grants. Aren't you making things even more difficult for medical schools?

A: Biomedical research support grants have provided minimally restricted funds for the universities over the years. Their elimination doesn't obviously strengthen the universities. It would have some impact. But the 1987 budget has also features designed to give top priority to investigator-initiated research grants, including a commitment to fund 18,000 research projects, which is a new expression of stabilization. I consider this a positive development.

Q: What do you mean by "stabilization"?

A: Stabilization has given me an opportunity to set a realistic target for NIH and the Congress with regard to new and competing awards and number of trainees. I realize the issue has caused concern in the scientific community, but from where I stand it has given the Congress the leverage to construct the NIH budget in a manner that allows more money for investigator-initiated research project grants and basic research.

Q: What are we talking about in terms of specific figures?

A: The percentage of the NIH budget that supports basic biomedical research is about 62 percent. It was around 30 percent 15 years ago. Each year during this period the Congress had added funds to the budget to bring us to the present level.

Q: But with respect to the 1987 budget, isn't the total number of NIH grants being reduced?

A: The 1987 budget has proposed a ceiling of 18,000 research grants starting in 1987. The number of new and competitive grants will be determined by the difference between continuation awards and 18,000.

Under this limit, new and competitive grants will be cut from 6,100 to 5,140. Because of the cuts and the average cost of a grant rising about 10 percent a year, which is higher than the rate of inflation, the NIH will not have the money to support 5,140 new grants at full cost. If we fund them at lower levels, we'll be changing the scope and character of projects, creating difficulties for the scientists involved.

Q: What are some of these difficulties and what do you propose to do?

A: When you reduce the scope of a project, initially that small cut will come out of supplies and other expendables. Seventy percent of the expense in a grant is personnel. About 4 percent is in equipment. You trim the supplies and it doesn't take long to realize you're not doing the job. If you, on the other hand, protect the supply category, the obvious alternative is to cut personnel. For these reasons I favor funding fewer projects but higher quality work and funding it adequately.

Q: From a personal standpoint how do you feel about these cuts, the future of NIH, and our national commitment to biomedical research?

A: I'm optimistic about it. Things are going to be tighter, but there's no question the administration is solidly committed to continued support of biomedical research, including basic research specifically. The Congress, both houses and members of both parties, view biomedical science and health-related research as a very high national priority.

Even the Heritage Foundation, which normally doesn't favor government expenditures for many things, feels the NIH fully warrants substantial government support for its value to health, for its contributions to development of new industries and the nation's economic well-being.

Now having said that, I don't think the NIH will be exempted from present fiscal constraints. We're not going to be treated in the same category as national defense or Social Security. There's no realistic possibility of that happening. But what the Congress does to the 1987 budget is an important bellwether.

-over-

A: We've heard this concern raised often. I'd like to make two points. When you look at the NIH budget between 1977 and 1985, the intramural programs grew 111 percent, the extramural 114 percent. There's some fluctuation between the two in given years, but overall their growth has been symmetrical.

My other point is that intramural programs have no citizen advocacy. We have to protect NIH intramural activities in our budget formulation. When the proposed budget is presented by the president in late January or early February before public hearings actually begin, the NIH intramural programs seem to have a higher priority.

But those who think so overlook the dynamics of the appropriations process. When reinforced by witnesses from professional societies, special disease agencies, and families of victims of disease, the Congress adds funds to the NIH budget each year. These go disproportionately to the extramural program, and the outcome is symmetrical growth.

Q: Many scientists think that NIH's intramural programs are generally first-class and match those one finds in academic centers. But there are also weak programs. How do you decide which intramural programs get funded and which do not?

A: We have an active review process by outside advisers for each institute. They review the work of laboratories and individual scientists every three years and recommend the level at which they should be supported. On that basis, some programs are expanded, others constricted.

Some university scientists would like to see prospective peer review applied to the budgets of NIH intramural programs, which is what they have to go through themselves. I'd suggest an alternative. Rather than saddle the intramural programs with all the encumbrances of the extramural review process, we should work on reducing the red tape for the extramural scientists. As I pointed out, we're trying to do that.

Q: In the United States there's a growing consumer movement demanding cost-effective and safer medical and surgical treatments. The safety and efficacy of many procedures can be established through careful clinical trials. Do you think the NIH has a responsibility to support clinical trials and if so, what will happen to those after Gramm-Rudman?

A: We have a responsibility in this area. We have supported clinical trials and they're a visible part of what we do. When the budgets are constrained, however, we can only fund a smaller number. The Congress asks many details about clinical trials. At the last appropriations hearing I cited 12 examples that had led to annual reductions in health care expenditures totaling $2.5 billion.

Q: Can you cite specific examples?

A: One was a clinical trial of the use of a drug called indomethacine for closure of patent ductus arteriosus in children. This condition occurs when the blood vessel that links the pulmonary artery and aorta before birth fails to close properly after birth. The leakage puts an additional strain on the baby's heart. The ductus or vessel can be severed and closed off in a surgical procedure. But there's now a less expensive approach, thanks to the work of Abraham Rudolph, professor of pediatrics at UC-San Francisco.

Rudolph had studied the physiological mechanism of the maintenance of the patent ductus in fetal lambs. He found that prostaglandins present in the ductal wall maintained the prenatal patency of the ductus of fetal sheep and that inhibitors of prostaglandin synthesis such as indomethacine caused constriction of the vessel. After the animal observations, studies with indomethacine were carried out in premature babies with patent ductus arteriosus. Such treatment for several days was followed by closure of the vessel in the majority of infants.

Subsequent clinical trials, supported by the National Heart, Lung and Blood Institute, found that 85 percent of children with that condition could be managed medically. The clinical trial cost $1 million, the cost of the medical treatment is about $40 per patient. The total savings of that innovation to the country is on the order of $200 million a year.

Another multicenter study, which sounds rather trivial, had to do with the criteria for tonsillectomy. The removal of tonsils had been performed almost ritually by physicians for decades. The study established new criteria leading to a remarkable decline in tonsillectomies nationwide. The Institute of Child Health and Human Development estimates the annual cost savings on the order of $800 million.

Q: What is your position on the pork-barrel projects approved by the Congress last year? The question refers to funding facilities for specific institutions bypassing the normal peer review process.

A: We don't have any official position on this issue. My personal view is that we'd like to see as many of these projects as possible subjected to peer-review. But the number of instances in which this review has been bypassed is not large.

Q: Various reports have suggested that as a nation we have not provided the necessary investments required to maintain university laboratories and equipment up-to-date. Do you plan to address this issue?

A: We're very concerned about it. The fraction of the NIH budget for equipment in individual grants has declined over time. Now it's about 2.9 percent of the average project award, and 4 to 4.5 percent of the total NIH budget, including large instrument funding programs. The NIH studied the shortfall in availability of large instruments that can be shared among two or more grantees. The shortfall was estimated at about $100 million per year. We've set a target of $20 million a year to alleviate that, and we're exceeding that amount every year. But we don't think the shortfall will be made up in five years, even though we're on target with respect to instruments costing $100,000 to $200,000.

Another study has indicated a very serious shortfall in small instruments costing between $5,000 and $60,000. The shortfall is greater in state-supported institutions, with a number of chairmen reporting that many research projects cannot be attempted because of the lack of instrumentation.

We've discussed this issue with the institute directors' advisory committee. Our sense is that our funding has fallen below the critical level and we need to address it.

Q: How can scientists help you in your efforts?

A: There's no country in the world that prepares its budgets for science the way ours does. It's important that our scientists understand the process and its politics. We at the NIH propose, defend, and appeal budget decisions, but there comes the time when the president's budget is formally presented each year. From that moment on I'm obliged to defend those decisions.

The special interest groups make their case to the Congress. The scientific community has the opportunity and obligation to make its case. But the effective way is to make it on altruistic grounds. It's not appropriate for scientists to make their case on the basis of personal pain. There's a lot of pain in the country. Our farmers are in trouble, small business people are suffering. Right now even the oil producers are in trouble. The idea that all scientists should be kept working, which is often the case made, I think damages the effort.

Q: In your opinion how does science fare in terms of public support?

38-YEAR-OLD, TERMINALLY ILL MAN, AWAITS A HEART-LUNG TRANSPLANT AT STANFORD UNIVERSITY HOSPITAL

STANFORD—

Facing grim odds, Doug Hoxworth, his wife, and four daughters wait optimistically and patiently for a donated heart and lungs, which they hope will give him a new chance at life. Doug is one of the 14 people currently on Stanford University Hospital's active waiting list for heart-lung transplants.

For Doug, who is 38 years old, this experimental surgery, if successful, is the only known cure for his lung disease, primary pulmonary hypertension. His need highlights a larger problem of insufficient organ donations to meet the large demand.

Selected from the hundreds of people who apply to the heart-lung program at Stanford, Doug considers himself fortunate to be on the waiting list.

The Hoxworths credit a chance meeting with Dr. Burt Groves from the University of Colorado's Hospital in Denver, who specializes in Doug's disease, as the key factor which brought them to Stanford.

Thinking that Doug would die soon, the Hoxworths went on a family vacation. On their final night, the Hoxworth's then-four-year-old daughter Katy precipitated this chance meeting with Groves.

It was then that Dr. Groves, said " 'I can't cure this disease, but I'll help you. I'm giving you a little light at the end of an otherwise completely black tunnel. I will get you into Stanford if it is possible to be done' and he did," Doug's wife Susan said. "That is the only way we got here," she said.

Doug met the program's stringent criteria for acceptance, which include being 55 or younger, terminally ill with cardiopulmonary disease, generally healthy otherwise, and having a stable family or psychological network.

The chances of someone getting on the waiting list, finding a donor in time, and surviving the surgery are slim. Of the 60 to 70 people accepted to Stanford's program since it began March 9, 1981, so far about half have received transplants, but one-third of those died within a month after the surgery according to Dr. Allen Glanville, Stanford post-doctoral fellow in pulmonary medicine. Several people have died while waiting for a suitable donor.

The average survival rate for those who live the first month, is 28 months, but "15 of these 21 long survivors are still alive," said Glanville. Doctors expect the survival rate to increase as the heart-lung program matures, he said. Mary Gohlke, the first successful heart-lung transplant and Stanford's first patient, is the longest survivor at five years.

Because of the lack of donors, people on the heart-lung waiting list must wait an average of 17 months to receive a suitable donor. Doug has been waiting seven months. His positive attitude helps him sit out the wait. "You have to stay mentally sharp and be careful of depression," he noted.

His chances of finding a donor may be better than others because of his average body size and common blood type, the two main factors in matching a donor and recipient, Doug said.

The Hoxworths wait with both anticipation and trepidation of receiving the phone call notifying them of a suitable donor. A call did come through Wednesday, April 9, at 3 a.m. The whole family went with Doug to the hospital, but after several hours doctors discovered a low-grade infection in the donor's lungs that made them unsuitable for transplantation. Turning back home was "really tough" on the whole family, Doug said.

Two other donors had been considered for Doug earlier, but those lungs also were inappropriate for transplantation, a common event, he said. Lungs are particularly delicate and prone to infection; thus, only about one in ten donors is suitable for heart-lung transplants. But, all is not lost; people waiting for heart transplants receive the hearts.

Doug, who describes himself as a former "workaholic," is a little frustrated staying at home and being so inactive, he said. But he is glad to have the opportunity to take a more active role as a parent, getting to know his daughters.

The Hoxworth's experience began two years ago in September at their home in Seattle when Doug realized he was getting short of breath doing normal activities like mowing the lawn and playing baseball.

"I figured I was out of shape," Doug said. Then in October 1984, he got what appeared to be an endless cold. Diagnosed as having the flu, Doug would "drag himself to work during the week and every weekend he was sick," Susan said.

His condition worsened. About four months later, after compiling "several pages of strange symptoms (including) a rash, swollen stomach, white toenails, bright purple knees, and a throbbing in his neck," Doug went to see an allergist, she said.

Numerous tests revealed an enlarged heart and the source of Doug's troubles was finally pinpointed. Doctors told him he had "a very bad case of primary pulmonary hypertension," Susan said. They also determined that he had "a few months or maybe even just a few weeks to live," she said.

Primary pulmonary hypertension is an uncommon disease, and the cause of it remains a mystery. It is characterized by defective blood vessels in the lungs leading to high blood pressure in the lungs and several other problems throughout the body. In particular, the right side of the heart may become irreversibly damaged because it works extra hard to compensate for the problem in the lungs.

The doctors in Seattle led the Hoxworths to believe that Doug's situation was hopeless. The family went through a "horrible" period of grieving, Susan said.

Then, "we decided to go on a trip to California in order to visit and say goodbye to friends and take the kids to Disneyland," Susan said.

The final night of their stay a woman who had been speaking with Katy on the steps of the hotel pool asked Susan why they were there. "I told her we were on our last trip because my husband was dying."

When she found he had primary pulmonary hypertension she was amazed, Susan said. At the time, she and her husband Dr. Groves were attending a symposium for cardiologists, and Dr. Groves was speaking on new treatments for primary pulmonary hypertension, Doug said.

As a result of this chance meeting, Doug went to Denver to participate in Grove's experimental program.

Their first visit to Denver was on April 7, 1985. After receiving oxygen and drug therapy, the rapidly deteriorating rate of Doug's condition lessened. And on September 9, 1985 Doug was officially accepted to Stanford's heart-lung transplant program.

"Groves said he had stabilized (the progression of the disease) a bit but there was no question that the only way he was going to make it was a heart-lung transplant," Susan said.

Doug came to Stanford immediately, and the rest of the family soon followed pulling a 6 by 12 U-haul.

The speed at which the events that led the Hoxworths to Stanford happened was remarkable, they said. "It usually takes forever to get anywhere," Susan added. "You are playing a game with time. Time is running out constantly and you are kind of running trying to keep ahead of it," she said.

Doug doesn't worry too much about it "I'm either going to make it or I'm not," he said.

FOR IMMEDIATE RELEASE

STANFORD SEES INCREASE IN ORGAN DONORS, CREDITS NEW STATE LAW

STANFORD—

Stanford has performed six more heart transplants—a 30 percent increase—this year than last, largely because California now requires hospitals to ask families for organ donations whenever a patient dies.

"We've definitely seen an increase in donors since the law's been in effect," said Marguerite Brown, R.N., donor coordinator for the transplant program at Stanford University Medical Center.

Twenty heart transplants and two heart-lung procedures have taken place since the state law went into place on January 1. Last year 14 heart replacements and two heart-lung transplants were completed during the same period. More than 380 individuals have received new hearts at Stanford, the largest heart transplant center in the world.

Despite the increase in transplants, "The rate still needs to be better," Brown said. "There's never an instance when someone isn't waiting for organs."

At all times, Stanford's waiting lists include eight to 10 persons needing hearts and 15 to 20 awaiting new hearts and lungs. About 25 percent may die before receiving new organs, and many more must be turned away from the program, Brown said.

According to estimates from the Regional Procurement Agency of Southern Califonia, about 10,000 persons are waiting for kidney transplants nationwide, 175 for livers, 150 for hearts and 30 for pancreases. Physicians have estimated that only 15 percent of organs able to be donated actually reach those waiting.

Heart transplants are now standard treatment for certain kinds of end-stage heart disease and are no longer considered to be experimental by the government and most insurance companies, Brown pointed out.

As part of national organ and tissue donor awareness week April 20-26, a special exhibit of transplant and donor information is set up outside the main cafeteria at Stanford University Hospital. Pamphlets and donor cards are available from the booth.

Following is general information made available by Stanford University Hospital to encourage organ donations:

When are donations made? Organ donations are made when patients have been declared legally brain dead—which means all brain functions have ceased—by two physicians uninvolved with the transplant team. Brain death is the standard, legal definition of death in California.

Many heart donors at Stanford are victims of accidents such as auto or motorcycle crashes, according to Marguerite Brown. Cornea, skin and bone can be donated under less traumatic circumstances, she noted.

-more-

After the family's consent is received, surgeons remove the organs under sterile conditions. The incisions are stitched and bandaged; the body is not disfigured and funeral arrangements are not delayed or altered.

How are organs matched to recipients? Organ recipients have been accepted into a transplant program and placed on a waiting list. Organs must be matched very carefully and quickly for biological compatibility and size.

What organs can be donated? The heart, combined heart and lungs, kidneys, liver, and pancreas. In addition, tissues such as the cornea, middle ear structures, cartilage, and skin—as well as bones—can be given.

Who can become a donor? Just about anybody. Persons over 18 years of age may fill out donor cards and tell their families of their wish to be a donor. The organs of children under 18 can be used only with the written consent of a parent or legal guardian.

Is there an upper age limit for donors? For transplant, yes. But some organs and tissues inappropriate for transplant can be used for research. For example, research done with corneal tissue has resulted in new treatments for glaucoma, advances in cataract surgery, and improved ways of storing transplant tissue.

What steps must be taken to become a donor? Persons who would like to donate organs should fill out and carry a signed Uniform Donor Card. The card must be signed in the presence of two witnesses aged 18 or older.

Families should be told of the desire to donate. Hospitals always ask permission from the legal next of kin and abide by the family's decision, whether or not an individual carries a signed card.

Donor cards are available from the California Department of Motor Vehicles, Nancy Manela of Stanford University Hospital Community and Patient Relations (415)723-7167, or donor coordinator Brown (415)723-5771.

Is the recipient told who donated the organs? No. To protect the privacy of donors and recipients, hospitals do not inform families of each others' names. The donor family is always told of the age and sex of the recipient, however, and is notified of the inital outcome of the transplant surgery.

Who pays for the organ donatione? There is no charge or payment for the actual organ donation: It is illegal to buy or sell human organs. Funeral expenses remain the responsibility of the donor family.

MEDICAL STUDENTS RECEIVE OVERSEAS OPPORTUNITY

STANFORD—

Stanford University medical students interested in research opportunities outside the United States can now apply under a new program for scholarships to underwrite their study and travel expenses, announced Dr. John Steward, associate dean for student affairs.

The Peter Emge Traveling Scholars Program will grant tuition credit, research assistantship salary for one quarter, as well as cover travel expenses to and from the site of study, Steward said.

About six traveling scholars are expected to be funded annually at first, Steward said Friday, April 18. An endowment has been created to provide approximately $36,000 a year to fund the program, he added.

"This program will give students an opportunity to view medicine in an entirely different context from the Western, tertiary care institution Stanford represents," said Dr. Gary Schoolnik, chief of the Medical Center's division of geographic medicine.

"Here (at Stanford), students see mostly intervention in established illness. In developing countries, public health practices and preventive medicine have a far more significant impact," Schoolnik added.

The Emge program is expected to help students pursue research opportunities in a wide variety of locations. For example, Schoolnik said his division is in the planning stages of establishing medical study programs in Chiapas, Mexico, and Shanghai, China, both potential sites for Emge participants.

Rules for participating are similar to the Medical Student Scholars Program which administers the Emge program. Scholars must identify a research project, submit a formal proposal and secure faculty sponsorship in order to receive academic credit. When the project ends, participants must present their findings in a report suitable for publication in the medical press.

The Emge Program commemorates the only son of Dr. Ludwig Emge, a German-born physician who chaired Stanford's Department of Obstetrics and Gynecology from 1931 to 1949. Peter Emge, a Navy fighter pilot, died in an accident in 1945.

The conference, scheduled April 20-22 at Hyatt Rickeys Hotel, 4219 El Camino Real, Palo Alto, is open to the news media. A news briefing featuring several conference participants has been scheduled from 11:30 a.m. to 1 p.m., Monday, April 21 at Rickeys. Reporters wishing to cover the conference or any of the sessions should check-in with the SCAN registration desk at the hotel (415-493-8000). Conference schedules have been mailed to the news media and are available in advance from the Medical Center News Bureau.

ADVANCE FOR RELEASE 11 A.M., MONDAY, APRIL 21

RESEARCHERS START HEART DISEASE PREVENTION WITH FOURTH GRADERS

STANFORD—

Using such concepts as "friendly fruit trees" and SPIN foods, researchers are studying if grade school children can be taught to reduce their cholesterol intake.

While findings are preliminary, nutritionist Anne Snyder is encouraged by recent efforts. Next she hopes to continue teaching children—and their families—about how to replace foods which decades later may lead to cardiovascular disease.

Snyder, a registered dietitian, said she is currently collaborating with the Stanford Center for Research in Disease Prevention (SCRDP) on a project to learn if a six-week program in elementary schools can encourage heart healthy eating.

The latest effort is based on the longer study which Snyder and colleagues at the Gladstone Foundation Laboratories for Cardiovascular Research conducted with third and fourth graders in the Milbrae, Calif., elementary schools in 1982-84.

Snyder was scheduled to discuss the study, called SPIN (Special Program in Nutrition), on Monday, April 21 at a conference of "Cardiovascular Nutrition." The two-day meeting for health and nutrition professionals is sponsored by Stanford Medical Center and the American Dietetic Association Practice Group of Sports and Cardiovascular Nutritionists (SCAN).

"We found that girls particularly showed statistically significant declines in (LDL) cholesterol, the blood component which has been linked to premature hardening of the arteries, heart disease and premature death.

Complete results of the study are expected to be published soon by Gladstone. Principal researcher was Dr. Thomas P. Bersot, assistant professor of medicine at UC San Francisco.

The SPIN study involved 27 weekly lessons for the grade school youngsters on how they could substitute healthy "SPIN foods" and reduce their intake of cholesterol-laden and other unhealthy items.

"In order to get their attention, we brought along treats of heart healthy foods. The children began to look forward to each session."

"The friendly fruit trees," for example, were bananas with a variety of fruit attached to toothpick branches. "The kids made them themselves and at the end of the lesson, they got to eat them," she said. "Another time we baked whole wheat pretzels and let the children twist them to their own initials."

In order not to scare the children or convey a negative message, children were told that high cholesterol foods were "sometimes" foods.

"The kids got the message quickly, said Snyder, that potato chips and such weren't taboo, they were something you ate only occasionally.

"Eventually, I'd have kids come up to me in town, and say, shaking their heads somewhat sadly, 'this whole day I had nothing but sometimes foods.'"

The classes were taught by the children's regular teachers. Snyder and colleagues occasionally would sit in on the class and act as a resource.

"We did want the children to understand the purpose of what we were doing, so we did talk about heart disease and showed them heart models." She said one session featured the school nurse dissecting and describing a beef heart.

The third grade age level was chosen, Snyder said, because the youngsters were old enough to read and become involved as consumers in food choices. She emphasized that evidence suggests that atherosclerosis begins in young children, so the benefits to be derived from the project were real.

Participating families attended regular evening meeetings so that parents could be involved in altering family eating patterns. Snyder said more than 90 percent of participating families in the project attended the evening sessions.

The SCAN conference, open to registered health professionals and the news media, is being held at Hyatt Rickey's hotel in Palo Alto. Sponsoring groups at Stanford include SCRDP and the Stanford University Hospital Department of Dietetics.

The conference features several nationally recognized cardiovascular experts, including Dr. Basil M. Rifkind, a cholesterol authority and researcher from the National Institutes of Health. He led the NIH-sponsored 10-year Coronary Primary Prevention Trial which in January 1984 disclosed that lowering blood cholesterol levels can reduce the risk of heart disease by as much as 49 percent.

Stanford speakers include Dr. Peter D. Wood, professor of medicine (research), who recently with colleagues completed a study which shows that diet and exercise are equally effective at lowering blood cholesterol. Also, Dr. William Haskell, associate director of SCRDP and associate professor of medicine, was scheduled to speak on "Is There an Exercise RDA (recommended daily allowance) for Good Health?"

ADVANCE FOR RELEASE 11:30 A.M., THURSDAY, APRIL 17

EDITORS: A press briefing with Senator John Garamendi and Dr. Lorrin Koran is scheduled for 11:30 a.m., Thursday April 17 in room 1190 of the State Capitol building in Sacramento. Senator Garamendi's office telephone number is (916) 445-2407.

CALIFORNIA'S MENTAL HEALTH SYSTEM LAX IN DETECTING PATIENTS' PHYSICAL ILLNESSES

STANFORD—

A Stanford University Medical School study has found that California's mental health system detects only half of the physical diseases requiring medical attention among its mentally disordered patients.

This means diseases that require medical treatment or monitoring are overlooked in about 22 percent of the system's patients, half of the 45 percent who have a significant physical illness, according to the study results.

The study was carried out by Stanford researchers as part of Senate Bill 929 sponsored by California State Senator John Garamendi (Democrat, 5th district).

This is the first time any state's mental health system has been surveyed in cross-section to find the incidence of physical disease among psychiatric patients, said Dr. Lorrin Koran, professor of psychiatry at Stanford University Medical School, one of the study's principal investigators.

Koran and Garamendi are scheduled to outline the study's results at a press briefing Thursday, April 17 in Sacramento.

The researchers studied 529 patients under care in eight mental health program categories—crisis intervention, psychiatric inpatient (24-hour acute hospital), psychiatric health facility (24-hour acute non-hospital), outpatient, day treatment (partial care), skilled nursing facility, community care, and state hospital. The study was carried out in Santa Clara, Santa Cruz, Monterey, and San Benito counties.

Koran said that overall the system seems to be doing a fairly good job of finding physical illnesses that directly cause patients' mental problems but it is not as effective in identifying diseases that may exacerbate or contribute to psychiatric symptoms, or in finding and caring for illnesses unrelated to a patient's mental health.

Thirty-two of the patients surveyed (6%) had a physical disease that caused their mental disorder, and the mental health system had identified 27 (5%), Koran said. But of the 49 patients (10%) who had a physical illness that exacerbated their mental disorder, the mental health system had recognized only 22 (4%), he noted.

Translated into statewide figures, these results suggest that undetected physical disease may be the cause of mental disorder in nearly 4,000 people being treated at state mental facilities, Koran said, and that nearly 15,000 patients may have undetected illnesses that compound their mental disorders.

4-16-86

- more -

In addition, patients whose physical disease was known to the mental health system were as likely to be receiving inadequate,or ineffective medical care (36%) as patients whose physical disease was not known to the system (34%), Koran said.

"The mental health system is not very active or is not very effective in helping mentally disordered patients obtain or cooperate with medical care," the study authors concluded.

"What the state should do on the basis of our results is a public policy question," Koran said.

"Some people say it's not the job of the mental health system to detect physical illness, nor to treat it. But I am of the school that says you can't provide high quality mental health care unless you're aware of the physical diseases that may be causing or exacerbating patients' mental health problems," he added.

Aside from neurological conditions such as epilepsy or dementia, examples of the kinds of medical problems that can cause or contribute to mental disorders include any disease with severe effects such as diabetes or asthma, endocrine imbalances such as hypothyroid conditions, migraine headaches, anemias, and severe vitamin deficiencies, Koran said.

Koran carried out the study with Dr. Harold Sox, Jr., associate professor of medicine at Stanford, and Dr. Keith Marton, now assistant professor of medicine at Harvard Medical School, in collaboration with other Stanford colleagues and with personnel from the mental health departments of the counties surveyed.

The researchers determined that the mental health system could raise its detection rate from 45 percent of diseases present in its patient population to 90 percent by screening with a mini-medical exam and evaluating the exam's results according to simple rules developed by the study team.

Such a screening program would cost $75-80 per patient as opposed to the $45-55 screening cost per patient now, but it would lower the state's current cost per sick patient identified from $205 to $150, Koran said.

The study did not answer whether or not the state would save money in the long run by putting into place a screening program that would improve disease detection ability, Koran said.

In the study's three-month follow-up period, no significant increase or decrease in mental health care costs or medical care costs was observed, Koran reported.

No increase was seen in medical costs, he noted, because the diseases detected could be treated on an outpatient basis and, in some cases, patients didn't seek care during the three-month follow-up period.

No change in psychiatric costs was observed because medical treatment for an underlying physical disease would not be likely to ease mental symptoms sufficiently for psychiatric care to terminate within three months, Koran said.

"Because the three-month followup period limited our ability to find some answers regarding long-term cost-benefits, we are recommending that the legislature fund several larger and longer studies to answer this and other questions," he said.

But in the meantime, the report also recommends the state institute a provision in licensing state psychiatric health facilities that requires "all patients admitted to a psychiatric health facility must receive a medical evaluation that includes a medical history and comprehensive physical examination."

-more-

Koran explained that the report's recommendations were developed by the authors in conjunction with the county mental health directors and their staffs, and with the SB929 policy advisory committee set up by the legislature and composed of representatives from the department of mental health and outside experts.

The group strongly recommended that the department of mental health educate staff at all organizational levels about the value of recognizing physical disease in mentally disordered patients, Koran said.

Most employees of the mental health system, such as psychologists or social workers, are not health care personnel, he noted, and generally they are not trained to recognize physical disease.

Koran and his colleagues also recommended that the department of mental health develop a "field manual" that could be distributed to county mental health departments, describing how to establish an effective medical screening program.

The screening procedure need only consist of 26 items of medical history that the patient can provide, a blood pressure test, and about 10 laboratory tests on blood and urine samples, Koran said.

By evaluating these items of health information and history according to a set of rules developed by the study team, the researchers were able to identify 90 percent of their study population's physical illnesses.

"This amounts to a doubling of the case finding rate for only about a 50 percent increase in screening costs," Koran said.

Since the medical history and blood pressure readings can be obtained by a skilled health worker such as a nurse practitioner, a physician's visit is not needed for such a screening program. And if the laboratory testing were done on a large scale, such as statewide, the screening cost per patient would be greatly reduced, he said.

The researchers looked into some of the barriers that might have prevented patients within the mental health system from seeking medical help. They found that one-fourth of the patient group under study hadn't consulted a doctor because they "couldn't afford to pay the bill."

Furthermore, those who experienced a financial barrier were much more likely to be physically ill than those who had not (54% vs 36%), much more likely to have had a previously undetected physical illness (27% vs 13%) and much more likely to have a disease related to their mental disorder (25% vs 9%).

As a result, the study recommendations suggest some actions designed to promote better medical care for mentally disordered patients. These include having the state ensure equal access to MediCal for those whose mental disorders impair their ability to complete application forms, and encouraging therapists and case managers to regularly update patients' medical records so as to help identify problems in obtaining or in complying with medical care.

AIDS VACCINE ON HORIZON BUT THERAPY STILL REMOTE, STANFORD PHYSICIAN SAYS

STANFORD—

Scientists have made impressive steps in the battle against the acquired immune deficiency syndrome (AIDS), "but we still don't have a therapy worth a darn," admits Stanford immunologist Dr. Edgar Engleman.

In a public lecture on April 14, Engleman stated optimism about the development of a vaccine in three to five years. "I believe we'll lick this thing through massive public vaccinations," he said.

Still, effective therapy is at least five to 10 years in the future according to Engleman, head of the Stanford blood center and an associate professor of pathology and medicine at the medical school. His talk, "AIDS: Past, Present and Future," was the final lecture in the three-part spring Progress in Medicine series.

The AIDS virus infects white blood cells known as helper T-cells, Engleman continued. "The helper T-cell sits in the middle of the immune system directing traffic and turning the immune system on when needed," he said. "Without that cell, the defense doesn't work."

Lacking adequate defenses, the body cannot fight common infections and patients die from other diseases. "It's a very painful, ugly and slow form of death," Engleman said.

The statistics are equally grim: More than 20,000 cases of AIDS have been diagnosed in this country; about half of those patients have died.

"Once the diagnosis of AIDS is made, patients aren't likely to live more than two to three years," he said.

But only 10 percent of the individuals infected with the AIDS virus have full-blown AIDS; about 200,000 to 2 million persons have been exposed to the AIDS virus, according to Engleman.

Why those persons remain healthy is not quite clear. The current AIDS test determines whether individuals have been exposed to the virus, but cannot predict who will develop the devastating collapse in defenses.

The AIDS virus has a long incubation period—an average of three years, although perhaps as long as seven.

"We don't know if there's a permanent carrier state," Engleman said, alluding to persons who could pass the virus on to others but never show its ill effects themselves.

Scientists have suggested two factors that may lead to the development of AIDS: "One is the dose of virus to which persons are first exposed," Engleman said, indicating that larger doses are more dangerous.

The second is the state of the helper T-cells before and after the AIDS virus comes on the scene. Helper T-cells activated to fight invaders become "more effective machines for producing and spreading the virus than resting cells," he said.

Promiscuous individuals—either heterosexual or homosexual—"have helper T-cells already stimulated by chronic infections," Engleman warned.

"But don't give up. It seems that a change in lifestyle can mediate the future," he said. Curtailing promiscuous behavior may not be "a full explanation, but we're hopeful."

more

4-16-86

2-2-2 Education and changes in lifestyle have dramatically reduced the spread of AIDS among homosexual men, Engleman pointed out.

But the promiscuous heterosexual population is probably at great risk of contracting the disease, he cautioned. About 75 percent of current AIDS patients are homosexual men, but men and women are equally susceptible to the disease, he said, pointing to evidence from Central Africa.

In Zaire in particular, he explained, equal numbers of men and women suffer from AIDS. Little homosexuality has been documented in that area, and heterosexual intercourse—with prostitutes in particular—has been implicated in the spread of the disease there.

Exactly why the disease is prevalent in that area and how it came to the western world still has scientists stumped. Some have speculated, however, that the AIDS virus is a mutant of an African monkey virus.

Vaginal and anal intercourse, contaminated needles and blood and blood products are the ways AIDS spreads best, Engelman said. The virus is found particularly in blood and semen, he noted, and infection seems to take place through direct introduction of those fluids into the blood stream.

"I'm pleased to say that no AIDS has been transmitted by blood screened at Stanford," Engleman said, "but I'm sorry to say that's not the case nationwide." Nationally, about 300 persons have AIDS as a result of receiving contaminated blood.

As the first blood bank in the country to screen blood for AIDS, Stanford was "criticized roundly" for its decision in July 1983. By 1985, all blood banks in the country were routinely testing blood for evidence of the disease.

The nation's blood supply is "very safe" from AIDS, Engleman assured the audience. Between the screening tests and huge public education efforts, "people at risk for AIDS know they're at risk and no longer donate."

Before the risk factors were known, individuals continued to donate unsuspectingly, Engleman said, but evidence indicates that is no longer true.

Because the current AIDS test has a high rate of false positives, additional tests should be conducted on blood screened out by blood banks, Engleman maintained.

Stanford conducts three tests before contacting individuals about their results; to inform persons of such damaging information requires certainty, Engleman said. Laboratories who test blood only once before informing donors are irresponsible, he charged.

Scientists are still perplexed by how the virus kills its host helper T-cells. "It doesn't make a whole lot of sense that a virus that wants to live a happy, comfortable life would kill the cell that houses it," he acknowledged.

Describing unpublished findings, Engleman said that Stanford researchers have shown that AIDS-infected helper T-cells have the ability to fuse to previously uninfected cells, creating giant, dying cells.

Competing theories exist, Engleman said, including one that asserts that the virus overworks the cell to death.

Engleman's collaborators in the cell-fusion research include Dr. Jeff Lifson and Barry Stein of Stanford, Dr. Mike McGrath of the University of California-San Francisco, and Dr. Greg Reyes of Gene Labs Inc.

RINGOLD RECEIVES ABEL AWARD

STANFORD—

Dr. Gordon M. Ringold, associate professor of pharmacology at Stanford University School of Medicine, is the recipient of the 1986 John J. Abel Award in Pharmacology.

The $2500 award is supported by Eli Lilly and Company of Indianapolis and is administered by the American Society for Pharmacology and Experimental Therapeutics.

Ringold was scheduled to receive the award at a ceremony April 16 in St. Louis during the Society's annual meeting.

The award recognizes "original, outstanding research in the field of pharmacology and/or experimental therapeutics," according to the Society.

Ringold, 35, joined the Stanford Medical School faculty in 1978. He did his undergraduate work at the University of California, Santa Cruz, and received a Ph.D. in microbiology in 1976 from the University of California, San Francisco.

His research focuses on the mechanism of action of steroid hormones.

MCDEVITT RECEIVES 3M LIFE SCIENCES AWARD

STANFORD—

Dr. Hugh O. McDevitt, Joseph D. Grant professor of medicine and chairman of medical microbiology at Stanford University School of Medicine, will receive the 3M Life Sciences Award on April 16 in St. Louis.

The $10,000 award, sponsored by 3M of St. Paul, Minnesota, honors "researchers whose work has made a significant contribution to the health and welfare of mankind."

McDevitt will receive the award at the annual meeting of the Federation of American Societies for Experimental Biology in St. Louis, Missouri, where he will also deliver the 3M Lecture, entitled "Genetic control of the immune response by Ia antigens."

McDevitt, 55, is distinguished for his work in developing a cellular and molecular explanation of how immune response genes function. His work has potential applications in predicting individual susceptibility to certain diseases and in the prevention and possible treatment of immunologically mediated diseases.

After completing his undergraduate studies at Stanford, McDevitt earned his M.D. from Harvard Medical School in 1955, and joined the Stanford faculty in 1966.

He has been elected to membership in several scientific societies, including the National Academy of Sciences, the Institute of Medicine, and the American Academy of Arts and Sciences.

McDevitt also has received numerous awards, including the 1977 Borden Award for outstanding research from the Association of American Medical Colleges, the 1981 Passano Foundation Award, the Albion Bernstein Award in 1983, the American College of Physicians Award for research in medical science in 1984, and, last year, the Lita Annenberg Hazen Award for excellence in clinical research from the Mount Sinai School of Medicine.

DECADES LONG TRACKING LEADS TO SPECIAL FONDNESS FOR NAMESAKE DISEASE

STANFORD—

Dr. Ronald Dorfman, a Stanford professor of pathology, has a fondness for studying a rather special disease.

True, most of his professional time is occupied researching and diagnosing widespread health scourges such as Hodgkin's Disease, and more recently, acquired immune deficiency syndrome (AIDS).

He is a noted hematopatholgist, an authority on cancers and diseases of the lymphatic system. He co-directs Stanford's noted and busy surgical pathology service, where he and his colleagues and students must confirm diagnoses of common ailments or seemingly one-of-a-kind maladies which have eluded physicians elsewhere.

In some ways the South African-born researcher is little different from many of his distinguished colleagues in meeting the triple-threat challenge of research, clinical care and teaching.

But he is unusual in a way that few of his clinical colleagues are aware of—a disease, for all the world to know, has been named after him.

"I travel all over the world lecturing on Rosai-Dorfman disease, but sometimes I'm surprised that most of my clinical colleagues here at Stanford have never heard of it," says a dry-witted Dorfman. He's not a bit angry that he is not a prophet in his own land. But he is concerned that more clinicians do not know about Rosai-Dorfman disease, because it may be misdiagnosed and treated improperly—with potentially dangerous results.

Rosai-Dorfman disease is a swelling of the lymph glands. It is a form of massive lymphadenopathy that in terms of symptoms resembles certain forms of cancer, which as a hematopathologist, Dorfman is intimately familiar with. But Rosai-Dorfman disease isn't malignant, and common cancer treatments such as radiation therapy don't affect its course and are not indicated.

The malady is rare, and there have been only about 300 documented cases in the approximately 25 years since Dorfman and former colleague Juan Rosai—now at the Yale University School of Medicine—began seriously studying the disorder. The condition is not fatal by itself, although the large tumors can seriously damage surrounding tissues or organs if the tumor is not removed. When the disease strikes the face, particularly in adults, disfigurement can result.

The cause is unknown, although Dorfman suspects that it might be a virus which affects persons who are genetically predisposed to suffer from the ailment. He continues to pursue research efforts but has no idea when a breakthrough may occur.

Sometimes surgery is necessary for cosmetic reasons to remove the rapidly growing tumor, but frequently the tumor disappears unassisted. Treatment is symptomatic and there is no known cure.

But the good news is that to the knowledgeable eye, it is easy to diagnose.

In lectures to students or discussions with colleagues, he is apt to take a minute or two to explain what the condition looks like.

"Once they've seen it, it's easy to differentiate it microscopically from cancer," he says. "But it is a matter of making students and clinicians aware of its characteristic features."

4-15-86

-more-

The rarity of Rosai-Dorfman disease was punctuated about 10 years ago when Dorfman presented details about a case at a Stanford University Hospital Tumor Board (a faculty patient care conference). Then and now, the disease is a rarity at Stanford—there have been only three documented cases in the Bay area, Dorfman said. Some of his other experience has come from the numerous consultation cases that have come from other parts of the country and from abroad.

At the tumor board, Dorfman was confronted by a skeptical Dr. Saul Rosenberg, professor of medicine and a noted oncologist, who recalled recently that he challenged whether such a large nonmalignant tumor was possible in the form Dorfman presented.

"The case was provocative," Rosenberg reminisced.

Dorfman's work on the lymph node condition later to be named for him began in the early 1960s in Johannesburg, South Africa. He was serving as a young pathologist with the South African Institute for Medical Research and a lecturer in the Department of Pathology at the University of the Witwaterstrand Medical School.

"I had the opportunity to see two young men with massive tumors. They were from rural areas, and our first thought, after ruling out malignancy, was an unusual lipid storage disease (a condition affecting the way the body processes fat). That turned out not to be true, and we remained puzzled even after the tumors receded and the patients improved."

Several years later and thousands of miles away, Dorfman was a faculty member in surgical pathology at the Washington University School of Medicine in St. Louis. He had brought with him the slides showing the unusual affliction of the two South African youths. One day his microscope revealed a familiar sight—another example of this rare disease.

"From that point on, I began to comb the case records at Washington University for similar examples. I found several, and soon I had enlisted the help of a bright, young research associate named Juan Rosai.

In 1969, the two doctors published a paper describing the condition. Included were case studies of four patients, the two South Africans, as well as two more cases from the files of Barnes Hospital in St. Louis where Dorfman and Rosai worked.

The two physicians called the disease "sinus histiocytosis with massive lymphadenopathy," referring to the first cases which involved enlarged lymph glands in the neck. Later it was found the disease could affect many organs other than lymph nodes, and the term "massive lymphadenopathy" did not always apply.

Informally, the disease became identified with its chroniclers, who in 1972, reported six cases in the journal *Cancer*. By 1981, other researchers began publishing papers referring to Rosai-Dorfman disease.

Dorfman recalls with some pride and satisfaction, the first time he saw his name as part of the title—not as an author—of a scientific publication. The benchmark piece appeared in the 1981 issue of Histopathology. Its arcane title: "Sinus histyiocytosis with massive lymphadenopathy (Rosai-Dorfman disease): report of a case with widespread nodal and extra nodal dissemination."

Dorfman chuckled when he recalled the first scholarly reference to his name was an afterthought to the generic, "sinus histyiocytosis with massive lymphadenopathy." Later articles—and a textbook chapter—refer directly to the malady as Rosai-Dorfman disease.

The disease afflicts mainly the young, with 62 percent of cases occurring in children younger than 10.

Although the first cases Dorfman identified were among poor blacks in South Africa, no particular races appear more likely to be affected by the disease.

USE OF ANGIOPLASTY, A NON-OPERATIVE APPROACH TO CORONARY HEART DISEASE, CONTINUES TO INCREASE

STANFORD—

Balloon angioplasty-a non-operative alternative to open heart bypass surgery- is gradually becoming a procedure of choice for up to half of all patients with coronary artery disease who require treatment, according to a Stanford University cardiologist.

The procedure is now used to treat over 100,000 patients annually, ten times the predicted number when it was first introduced nine years ago, said Dr. Stephen Oesterle, an assistant professor of medicine and director of Stanford University Hospital's unit for coronary intervention.

Angioplasty, also called percutaneous transluminal coronary angioplasty, is a procedure to re-open coronary arteries clogged with atherosclerotic plaques that form when mostly fats, cholesterol, and calcium accumulate in these arteries. These plaques constitute the essence of coronary artery disease.

In coronary bypass surgery -the alternative to angioplasty- a vein is removed from the leg and stitched into the coronary artery to bypass the plaque. This is a major open-heart operation.

"Patients prefer balloon angioplasty because it's so much simpler," Oesterle explained in an interview. "They don't have to be put to sleep."

Also, angioplasty costs about $5,000, nearly one-third the cost of bypass surgery and the hospital stay is about two days instead of 10, he said.

Oesterle predicted that balloon angioplasty will become the standard procedure, even though bypass surgery will continue to have its place in a number of very difficult patients.

Currently, angioplasty cannot be done in individuals whose coronary arteries have "funny angles," are inaccessible, or who have plaques that totally block the artery or extend over large areas. Bypass surgery is more appropriate in these people, Oesterle explained.

But, sometimes Stanford does angioplasty on patients that the surgeons think are inoperable, Oesterle said.

Stanford does approximately 200 angioplasty procedures and 500 coronary bypass operations each year. The reason Stanford's ratio of b*pass to angioplasty is not in accordance with the national 1-1 ratio is because so many "complex difficult (bypass) cases that nobody else wants to do" are referred to Stanford, Oesterle said.

Both angioplasty and bypass surgery "are for the relief of angina," pain due to insufficient blood flow to the heart, Oesterle said. But, it is not known if either of these techniques helps to reverse or retard coronary artery disease, he said.

more

4-15-86

Oesterle credits the rising use of angioplasty to major strides made in the technology. "We didn't get better all of a sudden," he said. Instead, "The equipment for doing this procedure has gone through three or four generations of change. And now, it is spectacular," he said.

Because balloon angioplasty has grown so quickly, there are many practicing cardiologists who have not received formal medical school or postgraduate training in the procedure, but want to learn about it, Oesterle said. These cardiologists look to major angioplasty referral centers "as the next best alternative" to learn about it. Stanford is one of the few major centers in the United States to put on yearly demonstration courses in angioplasty, he said.

Every year here, 300-400 community physicians spend three or four days learning about angioplasty by watching live closed circuit TV of doctors doing angioplasty, Oesterle said. "Over 1,000 physicians have probably watched live demonstration angioplasty on closed circuit TV here," he said.

With angioplasty, a catheter -hollow tube- is initially inserted into an artery in the right leg. Using a fluoroscope (a form of X-ray) to see, doctors gently push it into the heart's main vessel, the aorta. A tiny cylindrical balloon is then threaded through the catheter and maneuvered into the coronary artery where it is positioned across the plaque. The balloon is repeatedly inflated and deflated to squash the plaque into the wall of the artery.

In two percent of the angioplasties attempted, doctors are unable to complete the procedure because the plaques are inaccessible, Oesterle said. And, in another three percent of angioplasty patients, serious complications resulting in an emergency coronary bypass operation arise.

Complications occur when inflation and deflation of the angioplasty balloon cause the artery to collapse, blocking blood supplies to the heart. "That is a heart attack," Oesterle said.

"We have never had a death in angioplasty at Stanford. But, there is a clear-cut chance of death, probably around one percent," Oesterle said.

Due to the reappearance of plaques, in 20 percent of angioplasty patients a second angioplasty is required to have a lasting effect. Although this is an added expense and a nuisance to patients, those who do require it are usually diagnosed within three months after the first angioplasty, Oesterle said. And, the second angioplasty is almost always effective, he said.

Coronary artery disease mostly attacks men in their 40s and 50s. Researchers don't know what causes the build-up of plaque in the arteries, Oesterle said. Most people who get the disease have a combination of many risk factors, including family history, diabetes, hypertension, and high blood pressure, Oesterle said

But, "If you had to make a list of ten (of the most serious risk factors) the first eight would be smoking," he said. The rising incidence of coronary artery disease in women correlates with the rise in the number of women smokers, he said.

Stanford is currently doing a study to see if changing personal habits such as smoking, diet, and exercise can reverse or stop the course of the disease. The Stanford Coronary Risk Intervention Project (SCRIP), directed by Edwin Alderman, cardiologist and professor of medicine, will be the first study to examine precise changes in artherosclerotic plaques over a five-year period comparing the effects of aggressive intervention and non-intervention on coronary artery disease.

Editors, news directors, reporters:

ADVISORY

STANFORD—

A Cardiovascular Nutrition Symposium, featuring internationally recognized speakers and panelists, has been scheduled Sunday through Tuesday, April 20-22, at Hyatt Rickeys Hotel, 4219 El Camino Real, Palo Alto.

This is the third annual conference sponsored by the American Dietetic Association Practice Group of Sports and Cardiovascular Nutritionists (SCAN). This year the co-sponsors are The Stanford Center for Research in Disease Prevention (SCRDP) and the Stanford University Hospital's Department of Dietetics.

The conference is intended for health professionals, but reporters are welcome to attend sessions and interview participants.

An informal news conference featuring several speakers has been scheduled from 11:30 a.m. to 1 p.m., Monday, April 21.

The news briefing will permit reporters to meet with participating speakers, including Anne H. Snyder, consulting nutritionist for the Gladstone Foundation Laboratories for Cardiovascular Research, affiliated with UC San Francisco. Snyder recently was involved with a project which investigated in the Millbrae school system whether classroom programs can encourage third and fourth graders to choose heart healthy foods.

Snyder is scheduled to lead a seminar at 11 a.m. Monday, "Teaching Children Heart Healthy Eating," which is open to the media, and she will meet with reporters during the news conference starting at noon.

Among the conference speakers are Dr. Basil M. Rifkind, a cholesterol authority and researcher from the National Institutes of Health. He led the NIH-sponsored 10-year Coronary Primary Prevention Trial which in January 1984 disclosed conclusively that lowering blood cholesterol levels can reduce the risk of heart disease by as much as 49 percent.

Rifkind will be speaking on "Present Status of Cholesterol Lowering" at 8:15 a.m. Monday. He will also be participating in a panel, "Recommendations for Practice: the bottom line in Diet and Drug Therapy at 4:15 Monday.

Other guest speakers include Dr. Terry Kavanagh, medical director of the Toronto Rehabilitation Center and associate professor at the University of Toronto in Ontario, who will discuss "Exercise in Cardiac Rehabilitation: The Toronto Experience." Steven N. Blair, director of epidemiology, Institute for Aerobics Research, Aerobics Center, Dallas, will discuss "Exercise, Fitness and Hypertension."

Stanford speakers include Dr. William Haskell, associate director of SCRDP and professor of medicine, who will speak on "Is There an Exercise RDA (recommended daily allowance) for Good Health." Exercise physiologists have debated for many years whether there is an optimal level of exercise, and whether the benefits of exercise change and become deleterious beyond a certain point.

Dr. Peter D. Wood, another SCRDP associate director and a professor of medicine (research) at Stanford will discuss "Weight Loss and Risk of Coronary Heart Disease." Wood recently reported a study which showed that exercise and diet are equally effective at lowering cholesterol.

Reporters wishing to cover the conference or any of the sessions should check-in with the SCAN registration desk at the hotel (415-493-8000) to obtain free admittance to the conference and to learn room location of events. A conference schedule is available if not included with this advisory.

NURSING DEPARTMENT SCHEDULES 10-KILOMETER RUN

STANFORD—

Nursing research at Stanford University Hospital will benefit from the Patient Care Run scheduled at 8:30 a.m., Sunday, May 11 at Stanford Stadium.

Entry fee for the 10-kilometer (6.2-mile) single-loop romp through the Stanford campus is $8 before May 7. Race Day tickets at the starting line near Stanford Stadium will be available for $10, said Gaye Bruce, director of nurse recruitment and a spokesperson for the race.

Proceeds from entry fees will be used to fund research project involving nursing care, she said.

T-shirts will be provided for the first 400 entrants and may be picked up between 7:45 and 8:15 a.m. on race day. All finishers will receive ribbons and prizes will be awarded for the top three men and the top three women in the open and master (over age 40) categories.

Refreshments, including mineral water, oranges and chocolate chip cookies will be provided, Bruce said. Proceeds from the event will be used for nursing research, she added.

Entries may be mailed to the Department of Nurse Recruitment, Room C020, Stanford University Hospoital 300 Pasteur Drive, Stanford, CA 94305. For further information, call (415) 723-7261.

STERLING DRUG GRANTS STANFORD $50,000 TO ESTABLISH PHARMACOLOGY VISITING PROFESSORSHIP

STANFORD—

Stanford University School of Medicine has received a grant of $50,000 from Sterling Drug Inc. to establish a Sterling Drug Visiting Professorship in the Department of Pharmacology.

The grant was made in the honor of Dr. Maurice L. Tainter, noted pharmacologist, Stanford alumnus and former Stanford professor.

"I have known Dr. Tainter's work for years," said Dr. Tag Mansour, chairman of Stanford's department of pharmacology. "We're delighted to have this as a way of honoring a prominent scientist who served Stanford for 21 years."

Dr. Michael Silverman, clinical projects director at Sterling-Winthrop Research Institute, presented the grant to Mansour on April 14.

Proceeds from the endowment will help the school to invite a guest professor to the campus for a week every other year to present lectures, conduct workshops and seminars and participate in other educational sessions.

Established by Sterling in 1979, the Visiting Professorship program is designed to promote the interchange of knowledge between colleges and universities in the field of pharmacology.

Stanford expects to invite its first Sterling Drug Visiting Professor in the next academic year.

Tainter received his A.B., A.M., and M.D. degrees from Stanford University and went on to serve Stanford as a professor of pharmacology from 1922-43, leaving the university to join Sterling as director of research.

In 1946 Tainter established the company's key research center, the Sterling-Winthrop Research Institute; he directed the center for 15 years.

In 1946 Tainter also became vice-president of Sterling in charge of scientific affairs, a position he held until his retirement in 1969.

He is a life trustee and past chairman of the board of trustees of Rensselaer Polytechnic Institute; past member of boards of trustees of Albany Medical College and Albany College of Pharmacy; past president of the New York Academy of Sciences; and a fellow of the American Medical Association, among others. Tainter holds an honorary doctorate degree from Rensselaer Polytechnic Institute.

Tainter is widely known in the pharmaceutical industry as the author of numerous publications on medical and dental pharmacology, therapeutics, research administration and history of medical research.

Sterling Drug Inc., a New York City-based firm, manufactures and markets worldwide a broad range of pharmaceutical specialties, proprietary medicines, cosmetics, household and industrial products, and environmental controls.

CLINICAL SCHOLAR PROGRAM RECEIVES FUNDING RENEWAL

STANFORD—

A two-year fellowship program that permits physicians to expand their skills in fields ranging from law and economics to ethics and education recently was granted more than $1 million in a three-year funding renewal by the Robert Wood Johnson Foundation of Princeton, New Jersey.

Stanford and the University of California, San Francisco share funding and administrative responsibilities for the Clinical Scholars training program.

Examining risk factors that lead to heart disease and developing a computer program to help assess intensive care given to patients are projects currently being pursued by two of the five Clinical Scholars at Stanford.

Stanford Clinical Scholars completing their final year of study are Drs. David Maron and Adam Seaver; Drs. Lawrence Gottleib, Calvin Hirsch and Sylvester Quevado are currently in their first year of the program.

Since its start in 1974, the program has trained 419 physicians nationwide. These doctors are committed to clinical medicine, but have sought broader training related to the organization of health services, improvement of medical practice, and public policy in health, according to Dr. Halsted Holman, professor of medicine and director of the Stanford portion of the program.

Participants in the program attend seminars in such subjects as information sciences, sociology, cost-benefit analysis, anthropology and systems analysis to lay the groundwork for subsequent research. Faculty advisors for the Scholars are located on the Stanford, UCSF, and University of California, Berkeley campuses.

The joint Stanford-UCSF program is one of six Clinical Scholar programs funded by the foundation nationally. Former participants are involved in academic medicine, government and in the practice of medicine throughout the country, the foundation reports.

The program "allows physicians to develop skills in non-biological disciplines relevant to medicine," Holman said.

"Introducing non-biological disciplines into medical thinking and practice will not by itself resolve the problems of health care," Holman continued. "Nonetheless, these disciplines provide understanding and methods that are essential to the search for better solutions."

Other universities participating in the Robert Wood Johnson Foundation Clinical Scholars Program are the University of California, Los Angeles; the University of North Carolina, Chapel Hill; the University of Pennsylvania; the University of Washington, Seattle; and Yale University.

HUMAN MONOCLONAL ANTIBODIES AGAINST CHICKENPOX AND RH-FACTOR INCOMPATIBILITY ARE REPORTED NEAR

STANFORD—

Chickenpox and Rh-factor blood incompatibility are two diseases that within the next few years may be treated with monoclonal antibodies, protein "guided missiles" that can zero in on specific targets in the body, predicts a Stanford University scientist.

Scientists at the Stanford Blood Center—with other colleagues at Stanford—have developed human monoclonal antibodies that show promise as clinical agents against these conditions, although the experimental antibodies are still one to two years away from clinical trials, said Dr. Steven Foung, assistant professor of pathology at Stanford University School of Medicine.

Two of the new antibodies combat varicella zoster virus (VZV), the cause of chickenpox and shingles. Although chickenpox is a relatively mild disease that doesn't require special treatment in most normal individuals, it can be fatal in children with weakened immune systems, such as bone marrow transplant recipients and cancer patients, Foung said.

Another antibody could help prevent hemolytic disease of the newborn, a condition caused by Rh-factor blood type incompatibility between mother and child.

Administration of human blood serum is a current method for treating these two conditions, Foung explained. Anti-VZV antibodies present in serum can help to neutralize the virus in severe cases of the illness. Serum anti-Rh antibodies can also prevent an Rh-negative mother from mounting an immune attack against her Rh-positive fetus.

But there are drawbacks to using human blood serum, which is obtained from blood donors, Foung noted. One disadvantage is that donated serum is limited in supply. Another is that there is always a small chance of contamination from blood-borne diseases—such as hepatitis and other infectious agents—when using human blood products, he added.

In contrast, monoclonal antibodies can be made in large quantities in the laboratory and they are free of blood-borne contaminants, Foung explained.

Foung, who is also assistant director of the transfusion service at Stanford University Hospital, made his remarks Tuesday evening (April 8) in a public lecture entitled "Human monoclonal antibodies: potential use in therapy."

-more-

His presentation was the second in a series of three "Progress in Medicine" lectures sponsored by Stanford University Medical Center. The lectures deal with the impact of biotechnology on blood transfusion and transplantation.

Monoclonal antibodies are gaining uses in medical diagnosis and already have dramatically advanced certain areas of biomedical research, Foung said. They will begin to have a big impact on medical practice within two to five years, he predicted, and in treatment they are most likely to be useful in fighting infectious agents such as bacteria and viruses, Foung said.

Monoclonal antibodies are made by fusing two different types of cells. One cell has the capacity to produce a highly specific antibody protein that can home in on a target in the body—such as a virus—and mark it for destruction by the body's immune system. The other cell, which comes from a tumor, has the capacity to grow forever in the test tube. By fusing the two cells, scientists create an "immortal" cell that is capable of churning out large quantities of the highly specific protein.

It has been relatively easy to make monoclonal antibodies by fusing mouse cells in the laboratory, Foung said. But scientists would prefer to generate human monoclonal antibodies for treating patients, he added. Fused human cells are often unstable, however, a technical problem that has slowed progress in this field.

But Foung reported that he and his colleagues at the Stanford Blood Center have developed "an efficient system" for producing human monoclonal antibodies in the laboratory. First, they fuse a mouse and human cell together, and then they fuse that hybrid cell to a human cell in a second fusion process.

They produced the anti-varicella zoster virus antibodies and the anti-Rh factor antibodies, and others, using this system, Foung said.

The third lecture in the Progress in Medicine series will be held Tuesday, April 15 at 7:30 p.m. in the medical school's Fairchild Auditorium. Dr. Edgar Engleman, associate professor of pathology, medical director of the Stanford Blood Center and assistant director of Stanford Hospital's transfusion service, will discuss "AIDS: past, present, and future."

ARNOLD NAMED STANFORD HOSPITAL VICE PRESIDENT

STANFORD—

William Arnold has been promoted to executive vice president and chief operating officer of Stanford University Hospital.

In announcing the promotion, Sheldon S. King, president and chief executive officer of the hospital, wrote: "Mr. Arnold will continue to assume the responsibilities for the daily operation of the Stanford University Hospital. He and I work together as the Office of the Director of the Hospital and will continue to work as a team."

Arnold, 37, had been deputy director of the hospital since June 1984. He joined Stanford as assistant director in 1979 and was promoted to associate director and senior associate director before being named deputy director.

He received a master's degree in public health in 1974 from the University of California, Los Angeles, and served as an administrator of Cottage Hospital in Santa Barbara before coming to Stanford.

He and his wife, Joan, and two sons live in Portola Valley.

STANFORD AUTHORS CALL "BABY DOE" RULE GOOD-INTENTIONED BUT MISGUIDED AND INADEQUATE

STANFORD—

The federal government should stay out of medical decision-making in the intensive care nursery, recommends a Stanford University pediatrician.

In particular, the government's attempt to regulate medical care of disabled infants—the "Baby Doe" rule—is good-intentioned, but misguided and inadequate, contends Dr. David Stevenson, associate professor of pediatrics at Stanford University School of Medicine.

The government could much more effectively help the disabled by allocating more money for their medical expenses and rehabilitation rather than trying to manage their medical care, Stevenson suggested.

It is especially ironic for the federal government to try implementing such a set of rules at a time when it is cutting back severely on social programs to prevent and treat disability, said Stevenson, who is also an associate director of the newborn nurseries at Stanford University Hospital.

If the federal government wants to help handicapped individuals, it should provide adequate resources for their lifelong care and rehabilitation, Stevenson said. It should also provide education and care to pregnant woman about nutrition and other factors that could help prevent high-risk pregnancies, prematurity and disability.

He made his comments in an interview and in an article in the April 11 issue of the *Journal of the American Medical Association*.

Stevenson's co-authors on the *JAMA* report are Dr. Ronald Ariagno, associate professor of pediatrics (clinical) and associate director of newborn nurseries at Stanford Hospital; Jean Kutner, a Stanford undergraduate; Dr. Thomas Raffin, assistant professor of medicine and chairman of the Stanford Medical Center ethics committee; and Dr. Ernle Young, Stanford Medical Center chaplain and senior lecturer in medical ethics at Stanford Medical School.

The Reagan administration has supported the reinstatement of the Baby Doe rule, which was struck down in 1984 by an Appeals Court, as well as the passing of the related Child Abuse Amendment of 1984.

Among other things, the Baby Doe rule states that hospitals must provide the same care to handicapped infants as to non-handicapped babies, and it permits the federal government to intervene if parents and doctors are thought to be withholding care because of the existence of handicapping conditions.

In such cases, the rule makes provisions for government "squads" to obtain medical records and to conduct on-site investigations concerning an infant's treatment.

The rule also encourages hospitals to establish Infant Care Review Committees (ICRCs), composed of physicians, nurses, and lay people, who would make treatment recommendations concerning life-and-death decisions affecting seriously ill newborns.

Debate over the rule, which was drafted in 1982, reached the Supreme Court earlier this year. At issue is whether or not the rule, which was promulgated by the government under the Rehabilitation Act, is consistent with Congressional intent in passing that Act.

The Baby Doe rule is particularly inapplicable to the kinds of complex medical problems posed by very small premature infants such as those who weigh less than 1,000 grams at birth, according to Stevenson and his co-authors.

In these cases, the longterm outcome of lifesaving treatment for each infant is uncertain, and physicians often base their crucial decisions about care on the basis of what is medically in the best interest of the infant, not what is presumed to be morally good or bad from some arbitary perspective, Stevenson said.

4-7-86

more

All critically ill babies, especially those who are premature, are temporarily disabled and at risk for handicaps, he explained.

Since the distinction between handicapped and normal is so blurred, the Baby Doe rule's basic premise is flawed, Stevenson argued.

The regulations make the mistake of trying to simplify a vast range of complex medical cases into a few general categories, he added.

Treatment options for critically ill infants are not as simple as the Baby Doe rule assumes, Stevenson said. Although clear-cut solutions can be developed for a small number of handicapped babies whose medical conditions are easily identifiable, in most cases, there is no simple prescription for medical care.

This oversimplified approach will mislead people into believing there are simple answers to the care of critically ill infants, when there is actually "only ambiguity, equivocation and disagreement," he said.

"The guidelines do not resolve the uncertainties inherent in the practice of neonatal medicine and decisions about withholding or withdrawing life-sustaining therapies," the researchers wrote.

"Those of us who are really having to make these decisions and take care of these children are not helped by this rule," Stevenson said. "If people are led to believe that this rule has solved a problem, then it's a false belief. What's needed is more education and more financial resources to prevent and treat disability."

The rule is rife with ambiguous language and concepts, Stevenson added. "If people start suing each other over definitions of such vague terms as 'survival,' 'futility,' 'virtual survival,' and 'virtual futility,' then all it's going to do is displace a problem rather than address it head-on, by improving care," he said.

Another failing of the the Baby Doe rule is that it glosses over "the physician's commitment not only to maintaining the sanctity of life but to alleviating human suffering," the article points out.

If death is inevitable, then the risk of further injury to the infant enters into any consideration of withholding treatment, Stevenson explained.

Furthermore, it's impossible to consider an infant's "best interest" in isolation from social factors, including the family's circumstances and society's potential for caring for the infant, he added.

Another point Stevenson stressed is that most critically ill babies' medical conditions are so complex that physicians and parents usually aren't posed with a single monumental life-or-death choice but instead face numerous critical decisions daily.

It is unreasonable to expect that these kinds of choices—hundreds a day—can be referred to a committee for a decision, as the Baby Doe rule suggests, he said.

The establishment of infant care review committees also raises questions about the assignment of responsibility and legal liability for medical decision-making, Stevenson noted. "It's not clear whether such a committee has license to make medical decisions," he said.

However, an advisory committee can make sure all parties are able to air their concerns, he added.

Stanford University Hospital has had such a forum since long before the Baby Doe rule was drafted, he noted. This committee reviews cases when there is a difference of opinion about appropriate treatments among parents and/or those caring for an infant.

"We let all concerned express their opinions, but we still leave to the attending physician and the family to make decisions about what is appropriate for the care of the child," he explained.

The Baby Doe rule not only is inadequate but it is unnecessary, Stevenson added.

"It is not clear that the government...should implement a special moral code for the behavior of a group of licensed professionals (physicians) in addition to what has already been made explicit in the Constitution of the United States about the rights of citizens," the researchers wrote.

"In our opinion, a well-intentioned government attempting to practice medicine has mistakingly made itself vulnerable to violation of the medical maxim, *primum non nocere*, which means 'first do no harm'," the researchers concluded.

ADVANCE FOR RELEASE FRIDAY, APRIL 4, 1986

SCIENTISTS IDENTIFY GENES INVOLVED IN COLOR VISION

STANFORD—

Three human genes that specify the three pigments responsible for color vision have been identified and isolated by a scientific team based at Stanford University School of Medicine.

The work opens the way for the first direct studies of the color vision pigments and it suggests how color vision may have evolved, explained Jeremy Nathans, a medical student who is the principal author of two studies published in the April 11 issue of *Science* magazine.

The research also has enabled the scientists to pinpoint what goes wrong in color blindness, a condition that, in various forms, affects approximately eight percent of Caucasian men and one-half a percent of women.

Nathans is a student in the federally funded (National Institutes of Health) Medical Science Training Program at Stanford Medical School. A grant from the National Eye Institute also helped support the work.

His colleagues on the studies are Stanford biochemistry professor David Hogness, in whose lab he conducted the research, Darcy Thomas, a research assistant, Thomas Piantanida, a psychologist at SRI International in Menlo Park, and Roger Eddy and Thomas Shows, geneticists at the Roswell Park Memorial Institute in Buffalo.

Human color vision is based on three light-sensitive pigments found in approximately six million cone-shaped cells that line each eye's retina.

Scientists had previously deduced that each of these three pigments preferentially detects red, blue, or green light, and that during development a cone cell is programmed to produce only one of the three pigments, thus becoming sensitive to either red, blue or green light.

Scientists have also known that when a cone cell absorbs light it generates electrical signals which travel along a chain of nerve cells to the brain. We perceive different colors by analyzing the three color inputs. The exact color perceived depends on how strongly light excites each of the three types of cone cells.

But until now scientists had no way of determining the exact chemical structure of the color vision pigments, and no way of purifying the pigments for scientific studies.

-more-

Now Nathans and his colleagues have used the powerful tools of molecular genetics to isolate the genes—segments of human genetic material—that specify the three color vision proteins, and to begin analyzing the proteins themselves.

The work doesn't provide a treatment for color blindness because scientists don't know how to repair or replace defective sets of genes inside a person's body. But it does tell scientists exactly what is wrong.

Nathans and his colleagues proved that inherited red-green color blindness, the most common form of color vision disorder, is a result of rearrangement or shuffling of the red and green pigment genes. Scientists had previously guessed that red-green visual disorders would be traced to the pigment genes, but without the genes or the pigments at hand the hypothesis had been impossible to prove.

Many individuals with more severe forms of color blindness have actually lost either the red or green pigment gene, the scientists found. Some individuals with less severe color blindness have gained a new red-green hybrid gene.

The scientists also found that the genes for the three pigments are part of a "family" of similar genes that probably all were derived from an original "ancestral" gene. The family includes a fourth gene that pecifies a visual pigment called rhodopsin, which is responsible for nighttime black-and-white vision.

The scientists now also have shown that the genes for the red and green pigments are nearly identical in chemical structure, and that they probably evolved together fairly recently because they are located next to each other on the X-chromosome.

The genes for the blue pigment and for rhodopsin probably evolved earlier, Nathans said. They are located on different chromosomes and are less closely related both to each other and to the red and green pigments.

But rearrangments of the color vision genes don't always lead to a deficiency. People with normal color vision may have more than one green pigment gene, the scientists were surprised to find.

"The propensity of these genes to become rearranged may help account for the high frequency of color blindness in the population," Nathans said.

SCARCE BODY PARTS CREATE ETHICAL DILEMMAS FOR MEDICINE

STANFORD—

Advances in biotechnology have led to the development of techniques to successfully transplant living tissue, but society's failure to deal with these advances has created ethical dilemmas for physicians and patients, a Stanford scientist said Tuesday evening (April 1).

Dr. Carl Grumet, associate professor of pathology at Stanford University School of Medicine and director of the transfusion service at Stanford University Hospital discussed the "Sale of Body Parts: New Moral, Ethical and Biotechnical Dilemmas in Transplantation" at the first of three public lectures presented by Stanford University Medical Center.

One issue, he said, is the lack of donors from which vital organs--hearts, kidneys, lungs and bone marrow--can be procured for recipients. "How do we motivate people to donate?" he asked a crowd of about 300 community members.

In 1985 in the United States alone 6,000 kidney transplants were performed, he said, but another 10,000 people remained on the waiting lists, unable to find a donor. About 1,200 patients received bone marrow transplants during the same year, but again, more than 40,000 people who needed the transplants could not find suitable donors.

Heart transplants were performed in about 200 patients, Grumet continued, but an estimated 20,000-70,000 people who needed the life-saving procedure went without it because of a lack of donors.

The disparity between patients who need transplants and those who actually receive them is not due to a lack of potential donors, Grumet explained. Using kidney transplants as an example, he said that of 20,000 potential donors in 1985, only 15 percent of the organs were actually obtained for transplant purposes. A new California law requires physicians to ask families of patients who may be near death if they would, in fact, be willing to allow organs to be donated, but the overall picture has yet to improve.

An option some countries have resorted to is the selling of organs, Grumet noted. Selling kidneys is a fairly common way to upgrade one's socioeconomic status in India, he revealed, and a for-profit clinic that buys and sells organs exists in England.

In the United States, however, such practice is considered socially unacceptable. In fact, it's illegal. "There's the feeling that people would end up using coercion and other tactics to be able to sell organs purely for profit. Our society seems to be saying that organ procurement should be an altruistic endeavor," Grumet said.

Even if enough donors could be found, another issue is cost, a member of the audience pointed out. Grumet agreed. Even with the limited number of transplants, he said, Medicare spends about $2 billion annually on kidney transplants alone.

Another issue scientists are still grappling with is that of rejection. Medicine is developing and improving ways of dealing with the body's immune system, which can attack a foreign organ in defense. These methods include better donor and recipient matching techniques as well as irradiation and drug therapies that suppress the immune system enough to block rejection. Scientists are also working to develop tailor-made proteins, monoclonal antibodies, which can be manufactured to suppress the action of the immune system.

These antibodies will be the topic of the next lecture in the "Progress In Medicine" series. Dr. Steven Foung, assistant professor of pathology, will speak on "Human Monoclonal Antibodies: Potential Use in Therapy" on April 8. He will be followed by Dr. Edgar Engleman, associate professor of pathology and medicine, who will speak on "AIDS: Past, Present and Future" on April 15. The lectures are held in Sherman Fairchild Auditorium on the medical center campus, and they begin at 7:30 p.m. For more information, call 415-723-6389.

VIDEO CASSETTE WEIGHT-LOSS PROGRAM IS SUBJECT OF STUDY

STANFORD—

A weight loss and fitness program based on use of video cassettes will be the subject of a research study by Stanford University's Health Improvement Program (HIP).

HIP is seeking up to 200 volunteers for the 30-day program. Participants will be asked to deposit $150, but the total amount will be refunded when the program is completed and the cassettes are returned.

The cassettes present a mini-drama about a weight-losing family, along with nutritional advice and exercise programs. "It's like having your personal exercise physiologist, nutritionist and weight-loss counselor—all available on the TV set," said Keith Saylor, who designed the Stanford program.

Stanford University and Hospital employees and their families will be given preference in joining the program, but other individuals will be accepted if there are enough cassettes available. There are few restrictions, except that pregnant women will not be accepted and participants obviously must have access to a video cassette recorder with a VHS format.

Fran Carl, HIP program manager, said the cassettes were produced by a nationally known food corporation and the material was supplemented for the research study by Saylor, a graduate research fellow with the Stanford Center for Research in Disease Prevention. Dr. C. Barr Taylor, associate professor of psychiatry and an associate director of the SCRDP, is the principal investigator on the project.

"The study will help us evaluate the effects of mediated programs for weight loss," Taylor said. "Despite the tremendous marketing and sales of video-taped health programs, little is known about their effectiveness and how they can be made more useful. This program has been nicely designed to bring about behavior change and should be appealing to the subjects."

Carl said one group of participants will use the cassettes alone and another will be given supplementary educational material. A third group will serve as a comparison now and will start the program this summer.

The progress of the three groups will be evaluated and compared for the study. HIP intends to follow all participants for at least a year to compare the program variations for lasting weight loss.

Saylor said the cassettes depict 30 days in the lives of three actors portraying a typical family: a mother, a father and a teen-aged daughter. All of the actors were slightly overweight, he said, and actually lost an average of 10 pounds each during the 30 days by following the prescribed routines and eating the recommended foods.

Besides the main cassettes, which present the story line and advice from experts on dieting and nutrition, there is an exercise cassette. Saylor said the exercise routines offer participants the chance to try for basic, intermediate or advanced levels of fitness.

HIP plans to start the program with a series of meetings from Monday, April 14, through Friday, April 18. Attendance at one of the meetings is mandatory and a place can be reserved by calling (415) 723-9649.

STANFORD GROUP NAMED FIRST HEALTH PROMOTION CENTER

STANFORD—

The Kaiser Family Foundation has named Stanford as the first of four centers to participate in a multi-million dollar program seeking to reduce preventable health problems and premature death.

"For the first time, the principles of community-based health intervention are going to be made available to people—first in the 13 Western states—and then nationwide through a cohesive and integrated project," said Dr. John W. Farquhar, professor of medicine and director of the Stanford Center for Research in Disease Prevention (SCRDP).

SCRDP's role as the first health promotion resource center in the foundation's Community Health Promotion Grant Program was scheduled to be announced Wednesday at a campus news conference by Farquhar, who will direct the center.

Simultaneously at a Washington, D.C. news briefing, Alvin R. Tarlov, president of the Menlo Park, Calif.-based foundation, unveiled plans for the program. The foundation has committed $15 million for the first three years of the program. He said the project would target five major health problems—heart disease, alcohol misuse and drug abuse, teen-age pregnancy, cancer and injuries.

"Because the target health problems are rooted in the popular culture, they will require comprehensive and prolonged community-wide efforts for their solution, which can come about through education aimed at altering personal behavior and societal practices," Farquhar said.

"Preventable illness and injuries claim nearly 1.3 million American lives and cost the nation more than $300 billion each year," Tarlov said.

The foundation president noted that 90 percent of all injuries are considered preventable, and injuries are the leading cause of death for persons under 44 years.

"It's obvious that community action and education can make a profound difference in reducing the 180,000 accidental deaths which occur in this country annually," Farquhar said. "The impact will be especially strong in reducing those accidents which are also linked to substance abuse."

Stanford and the SCRDP were selected as the site of the first Resource Center because of its 15 years of experience with community-based cardiovascular disease prevention, Tarlov said.

"We are grateful to the foundation for making available to a wide segment of the public the fruits of the research into community health intervention that have been carried out here and elsewhere for the past 15 years," Farquhar said.

The SCRDP, an outgrowth of the Stanford Heart Disease Prevention Program, has gained national attention for its community programs which use a variety of educational and environmental change approaches to help choose healthy lifestyles.

4-2-86

-more-

Some of the approaches studied and implemented by SCRDP have involved community support groups, programs which help companies set up exercise or health education programs for employees, pamphlet education campaigns on nutrition, and television announcements or programs focusing on healthy living.

Many of the Stanford education programs have been concentrated in Monterey County, and have shown that a significant reduction in health risk can be achieved. For example, a recent study presented by SCRDP to the American Heart Association showed that by using a variety of educational approaches in a community, smoking can be decreased dramatically.

"The (Stanford) Center will provide important guidance to communities developing health promotion projects in our program. As we embark on the Kaiser Family Foundation Health Promotion Program, we are pleased to have Stanford as a partner," Tarlov said.

Stanford received $307,198 for six months to develop the center, and additional grants will support its operation over the next several years, Farquhar said.

As a Health Promotional Facility, Stanford is expected to provide technical expertise and support for community health projects, including development and production of training materials, training of volunteers and staff workers.

Tarlov said selected communities would be invited to apply for matching funds up to $150,000 per year from the foundation. Also, he said resources and expertise of the Stanford center would serve communities supporting their own projects.

Examples of community-based projects that might be supported in the foundation's program include tobacco, alcohol and drug abuse prevention programs for junior and senior high school students, or an education and social support project to reduce adolescent pregnancy.

Tarlov said the first projects are expected to be launched in the Spring of 1987. Prior to that, the Stanford center will host a campus conference July 17-19 for community leaders interested in health promotion.

Dr. Wendy Everett Watson, program director for the foundation's project, said priority for funding will be given to projects that focus on the social or environmental factors that have major impact on health behavior.

She said priority also will be given to projects that pay special attention to making healthy habits more feasible for communities with large low income and minority populations. Farquhar cited as an example Stanford's effort in Monterey County to help low income Spanish-speaking rural residents develop a balanced diet using traditional Mexican menu items.

The program requires applicants to form a coalition of organizations, encouraging active participation from broad segments of the community, including schools, churches, worksites, health care organizations and voluntary agencies.

Initial applications for grants would be limited to community groups in Alaska, Arizona, California, Colorado, Hawaii, Idaho, Montana, Nevada, New Mexico, Oregon, Utah, Washington and Wyoming, the foundation said.

At Stanford, Farquhar will be assisted by SCRDP research associate David Altman, Ph.D., who was named associate director of the project, and June Flora, Ph.D. education director of SCRDP, will function as liaison to the foundation for the project. A faculty advisory board is also being created and additional staff members have been assigned or recruited, Farquhar said.

96-YEAR-OLD MAN GETS NEW KNEES AT STANFORD HOSPITAL

STANFORD—

Elzy Benson, a 96-year-old man, will walk away from Stanford Hospital Wednesday, April 2, after having had a bilateral knee replacement operation just 15 days earlier.

He is the oldest man believed to have undergone this type of operation at Stanford hospital.

Those new knees will bring renewed joy to his hobbies, fishing, hunting, and photographing the landscape, which he plans to continue when he returns to his home in Fowler, Calif., "ten miles south of Fresno," he said. His 91-year-old wife Agnes and a new camera await his return.

The operation was done to relieve the pain in Benson's knee joints caused by worn-out cartilage, a natural result of aging. One knee had been bothering Benson for three or four years, and recently the second knee began troubling him, he said. After a friend recommended that he have the operation, "I decided I had better have it done before I hurt myself," he said. Since surgery, "I have had no pain at all," he said.

The operation is basically a resurfacing of the bones with "specially manufactured materials" that imitate natural cartilage, said Dr. David Schurman, associate professor of orthopedic surgery, who performed Benson's operation.

The operation is similar to hip replacements, Schurman said. However, although artificial knees are more durable than artificial hips, they will "never allow someone to completely squat," he said.

During Benson's post-operative recovery at Stanford, a machine slowly and constantly moved his knees up and down, even while he slept. "You get used to it, you have to," he said.

Benson has had to get used to a lot of changes in his lifetime. "I'll never be able to understand all this electronic and computer stuff, but the younger generation can't get along without them."

To him the changes in the medical profession are astounding. "I can remember when diphtheria would come through and kill off every youngster," he said. Today, diseases such as diptheria are rarely seen in the United States.

"It is unbelievable what doctors can do today; look what they did to my knees," he gestured.

This surgery is common in elderly people, but it is also done in young people who have rheumatoid arthritis or multiple problems, Schurman said. Fixing both knees during one operation rather than two is unusual, although every indication shows that one operation is safer than two, Schurman said.

4-1-86 -more-

Approximately 40,000 people have knee replacements every year. Stanford does about 100 each year.

How does Benson account for his good health at his age?

"You just can't figure it," he replied. It may be related to the fact that "I never had a cigarette in my mouth (and) I wouldn't drink 6 oz. of liquor for $1,000," he said. He eats lots of fresh and dried fruit, lots of raw vegetables, and plenty of bread and milk, but he does not enjoy meat very much, he said. Through his experience he has found that it is very important to keep your mind working as you age, Benson said.

The Bensons were married in 1915. Mrs. Benson is renowned for the award winning flowers she grows in their back yard. "It is unbelievable what the woman can do for flowers," Benson said.

Benson was born in 1890 in Grahm, Texas. He and his family "were pioneers in the early days," he said. When he was nine years old, his mother died of typhoid fever. This left his father, who also had the fever, stranded in an eight-by-ten log cabin on a homestead in New Mexico with three boys and a girl, he said. "Finally Daddy was able to drive (the 500 miles) back to Texas" in a covered wagon during December, Benson said.

As a youth, he moved to California with his family; they also traveled here in a covered wagon, he said.

He has lived in Fowler since1903, he said.

Through his long time interest in photography, he has accumulated a large collection of photos of the area, some of which were taken from the earliest technology when "we had film stuck onto glass plates," he said.

He suggested that someone compile a book based on his longtime knowledge and pictures. "Somebody ought to get it all out of me, while I still can do it," he said.

EDITORS: This story is based on an interview with David Packard, chairman of the White House Science Council's panel on "The Health of U.S. Universities and Colleges." The panel's report will be formally released in a few weeks. Brief accounts on the panel's recommendations have appeared in various publications. An edited text of the interview accompanies this story.

PACKARD CALLS O.M.B. PROPOSALS TO CUT RESEARCH COST REIMBURSEMENT 'SERIOUS MISTAKE'

STANFORD—

David Packard, chairman of a panel of the White House Science Council Tuesday, April 1, called Office of Management and Budget (OMB) proposals to reduce federal research cost reimbursement to universities "a serious mistake."

"The government should increase funding of basic research at universities and colleges even if total federal spending for R & D is reduced," the former deputy secretary of defense said in an interview.

In a forthcoming report on "The Health of U.S. Universities and Colleges," the panel will recommend that academic institutions be allowed a faster writeoff on buildings and equipment used in federally sponsored research.

The Hewlett-Packard board chairman saidthe OMB proposals designed to limit reimbursement of administrative overhead costs were "out of tune with what is really needed."

"The OMB did precisely what we recommended they not do," Packard added.

The implementation of OMB's rules was postponed for two months after widespread criticism by university leaders.

The White House panel emphasized its suggestions should be considered as "an integrated package. It would be calamitous," Packard noted, "if the implementation of our recommendations resulted in decreased funding for university research."

But the OMB, presumably looking for ways to reduce the administration's budget, picked up on the administrative overhead issue, ignoring other council recommendations designed to increase substantially the indirect fraction of those total research costs, Packard said.

The federal government, the panel found, is not paying the full costs of research now. "In suggesting a fixed administrative overhead allowance," Packard said, "we also recommended important measures to inject reality into the way research costs are identified and paid for."

The support of university research is "actually an investment, not a commodity that can be bought," the panel said.

The OMB's controversial rules, originally scheduled to take effect April 1, would cap administrative overheads on federal grants to universities at rates of 26 percent this year and 20 percent next year. The changes, according to Stanford University President Donald Kennedy, will cost research universities $300 million annually, with about 40 percent of the loss concentrated in 10 institutions.

The OMB made the changes without the customary negotiations with the universities, and last week, confronted by a flood of protests, it announced it would delay their implementation. But in Packard's words, "The OMB lacks any understanding of what the problem is all about."

"I'm going to talk to them myself and see if we can get this thing turned around," he added.

4-1-86 -more-

The panel's recommendations rest on the premise that the universities have been seriously constrained by insufficient and uncertain funding, and their operations have been increasingly tied up in bureaucratic red tape.

"At a time when we expect much of our universities," the report notes, "we find them at the end of more than a decade of retrenchment and belt-tightening. This is reflected in obsolete equipment, aging facilities, and growing shortages of both students and faculty in many important fields."

The report suggests ways in which federal and university relationships can be streamlined to become more cooperative and productive, and calls for significant increases in research support.

One area in need of increased support is research facilities and scientific equipment. The report recommends that a new fund be established in the National Science Foundation for each of the next 10 years to which the universities can submit proposals. Monies will be awarded on the basis of peer review based on merit and would have to be matched with nonfederal funds.

The report also recommends a shift to longer-term grants and contracts, with a duration of "at least three and preferably five years." It suggests that researchers be allowed to use up to 10 percent of their funds on a discretionary basis to support activities not necessarily covered by the grant.

"We felt it was desirable to extend the period of the grants to introduce stability in the way the government supports university research," Packard said. "We pointed out that research groups are fragile. Once they are disbanded they cannot be easily reassembled."

Because the panel found considerable friction and controversy regarding indirect costs of research, its report called for a fixed ceiling on the portion of those costs related to administration to be phased over a two-year period. However, it also called for offsetting changes in other indirect costs that in Packard's words "would allow the universities to recover their full costs."

Among the recommended measures are changes in the manner in which research costs are determined, including a new formula for a more rapid depreciation of buildings and scientific equipment, elimination of faculty effort reporting, and a reorganization of the federal tax code to encourage increased industry-university interaction.

Quoting from the report, Packard said it is in the national interest that a "healthy university system" be maintained. Universities must rank first in government priorities for allocating research and development support, he said.

He added that in 1984 the federal government spent $100 billion for research and development, but only $8 billion of this was spent for university research.

"Much of the R & D budget is for military research which is not relevant to strengthening the basic science of our country," Packard said. "We pointed out that this is not commensurate with the (research) demands being placed on the universities."

"The government," Packard continued, "is asking universities to participate in research on a cost-sharing basis by failing to provide adequate allowances for depreciation of buildings and equipment. Both of these have deteriorated and their replacement value, owing to age and inflation, has gone up much more rapidly than is generally recognized."

Packard said the panel agreed the federal government should pay the full costs of university research. "It should do so because the country in the long run has a stake in the health of the universities," he said.

Asked if the panel's call for increased research support is realistic in view of the federal deficit, Packard said, "Our recommendations can be implemented without any increase in the overall pool allocated for research and development.

"We have said the major federal agencies—the Defense Department is a good example—should use more university research resources than they do now, and they should make it much simpler to enter into research contracts with universities.

"If you look at the $100 billion now spent for research, and realize that only a small fraction of it reaches the universities, even if total federal spending is reduced, there's still plenty of money for what needs to be done."

Packard said university research is important for two reasons. "It provides the improvement in our store of basic knowledge on which everything will be built in the future," he said.

"The universities are the source of our scientists and engineers for the future. We've pointed out that the demand for new talent and new knowledge have never been greater and that our universities will not be able to respond to these growing needs without an increase in federal support.

"In essence, we are saying we ought to put more into the seed on which we're going to depend on in the future as a nation. There's no reason why this can't be done if it's simply recognized.

"I think the Congress will be sympathetic to this."

Packard, who also chairs the President's Commission on Defense Management, said the commission in its final report will add a provision requiring the Defense Department when appropriate to make more effective use of university resources for basic research.

"Despite our difficult financial situation, I believe things can be done to improve the overall position of our universities," he said.

The science panel, co-chaired by Yale University physics Prof. D. Allan Bromley, was asked in a 1984 White House memo to recommend new principles for improving relationships between the federal government and universities.

There was concern whether these relationships were adequate "to create the scientific and technical talent and to conduct the research needed to sustain America's leadership in industry and defense," the memo said. "The Council should provide a tautly reasoned policy statement, which would serve to guide federal actions with respect to universities and colleges."

"The panel has done what was asked," Packard said. "Now the scientists and the universities must try to do their part because they share some of the responsibility."

Echoing some of the panel's conclusions, Packard said scientists and engineers must become informed on the problems and challenges faced by the nation. "Each supporting voice counts and can make a real difference."

Universities must also try to reduce costs whenever possible, Packard said. This means being prepared to make hard choices, to operate within the levels of external support available.

—30—

This is the edited text of an interview with David Packard, chairman of the White House Science Council's panel on "The Health of U.S. Universities and Colleges." The panel's report, which will be formally released in a few weeks contains recommendations for building a more solid and enduring partnership among the federal government, industry, and universities to enable the nation to keep pace with research and educational needs

Q: Why did the Reagan administration ask the science council to review the relationships between the federal government and the universities?

A: There's concern about whether or not the United States is keeping pace technologically with Japan and the European nations. One area the council had looked at earlier was the federal research laboratories. There are 700 of them and some are doing good work, but in many we found the research to be clearly unrealistic and non-productive. We recommended that our federal laboratories have closer ties with the universities where most of the fundamental research is done.

As a result of this work and that of the Commission on Industrial Competitiveness, headed by John Young (Hewlett-Packard president), we got back to the basic proposition that universities in the United States have very fundamental roles in generating the basic knowledge in all areas of science and technology on which the prosperity of our country depends, and in training the scientists and engineers for the future.

We felt, therefore, the federal government should review its relationship with the universities, and try to establish an even more productive one. In deciding priorities for allocating research support, for example, we think universities must rank first.

Q: Was the council's inquiry only limited to issues of science and technology?

A: No. We recognized that the contributions of our universities in the humanities and other areas were also very important and significant. We've stated the health of the entire spectrum of American higher education which trains young minds—from chemistry to the classics—is essential to our national future and that science cannot be viewed in isolation.

Q: What were some of the problems you discovered with respect to research?

A: The federal government is in fact not paying the full costs of university research. We've been reminded the United States still has one of the strongest science and technology enterprises in the world. Yet at a time when we expect much of our universities, we find them at the end of more than a decade of retrenchment and belt-tightening. As our report indicates, this is reflected in obsolete equipment, aging facilities, and growing shortages of both students and faculty in many important fields.

In the absence of significant changes in the relationships involving universities, industry and the government, the universities we think won't be able to meet the growing demands made on them in an increasingly techological and competitive world.

Q: What do you mean by "the federal government is not paying the full costs of research?"

A: The government is asking the universities to participate in cost-sharing. It doesn't provide, for example, adequate allowances for laboratory buildings and equipment which are deteriorating because of age, deferred maintenance, and just plain obsolescence. On top of these, inflation has caused their replacement value to go up more rapidly than it is generally recognized. We think the government should pay the full costs because university research is actually an investment, not a commodity that can be bought. The government has a great stake in the health of our universities.

Q: What should be done to enable the universities to meet society's demands?

A: We think the federal government and the private sector should make significantly greater investments in our universities in the 1980's and 1990's than in the 1970's. Our recommendations require increases in financial support. We're suggesting that a facilities fund be established in the National Science Foundation for each of the next 10 years to which the universities can submit proposals. The monies will be awarded on peer review based on merit, and would be matched 50/50 with non-federal funding.

We've suggested a shift to longer-term grants and contracts with the duration of at least three and preferably five years, and we added that scientists be allowed to use up to 10 percent of their funds on a discretionary basis to support activities not necessarily covered by the grant.

These changes are desirable because many of our talented people are wasting their time writing grant proposals. Research, our panel agrees, requires long lead times for preparation and incubation. Research groups are fragile. Once they are disbanded, they cannot be easily reassembled. In the absence of stability, important talent and research opportunities have been lost, and this is sad.

Q: What do you think of the caps on the administrative overhead that were proposed recently by the Office of Management and Budget (OMB) in Washington? You've recommended that the decade of university retrenchment and belt-tightening be turned around. Is the OMB out of step with your proposals?

A: The OMB did precisely what we recommended they not do. We said clearly our recommendations should be considered as an integrated package. We said it would be calamitous if their implementation resulted in decreased funding for university research. In picking one item out of the report— namely that payment of administrative costs within the indirect cost category be capped at a uniform percentage—I think the OMB has made a serious mistake. I'm going to talk to them myself and see if we can get this thing turned around. What they've done is out of tune with what is really needed.

Q: You said the council's proposals should be considered as an integrated package. In what way do you see this as helping the universities?

A: The panel was concerned about the friction associated with the reimbursement of indirect costs and the variation in overhead percentages among the universities. We felt everyone would be better off if we could agree on a reduced fixed allowance for the administrative components of overhead coupled with measures that would actually inject reality into the way research costs are identified and paid for.

Q: Can you describe some of these measures?

A: We suggested, for example, a realistic formula for determining depreciation allowances on buildings and scientific equipment. These we think should be based on true useful lifetimes. Useful life for buildings and facilities should be reduced from the present level of 50 years to 20 years. Useful life of equipment and instrumentation should be cut from 15 years to 5 to 10 years, depending on the equipment.

We recommended that the requirement of cost-sharing be eliminated, the paper work associated with grant and contracts be cut to a minimum, and the faculty effort reporting eliminated entirely. We thought the practice of the National Science Foundation, which requires overhead costs to be part of the project budget subject to peer review, was useful and should be adopted by all agencies supporting university research. We said also that much could be gained in efficiency if all agencies made greater use of block grants or contracts to support groups of researchers who have shared interests.

These were specific recommendations of the panel designed to increase substantially the indirect fraction of those total research costs.

Q: Your report mentions the importance of private industry in supporting university research? How can this participation be encouraged?

A: The relationship between basic research in the universities and the health and welfare of new industry is extremely important. Our universities have generated a very large amount of our basic knowledge. This knowledge has been instrumental in meeting our goals as a nation, be they industrial development, national security, health, agriculture or the improvement of the quality of life of our citizens.

We've recommended that any reorganization of the federal tax code should encourage greater industry-university interaction. We think that a 25 percent nonincremental tax credit should be set up for industrial funding of university research and for industry-supported servicing of university equipment. We also have suggested a merit-based scholarship program be set up by the government and a separate one by industries that depend on university research and education. The goal would be to support the most able one percent of the undergraduates in mathematics, engineering, and the natural sciences entering colleges or universities each year.

Q: With the administration concerned about cutting the federal deficit, how optimistic are you that your proposals will be implemented and why?

A: I think they can be implemented without increasing the overall pool of money available for research and development. You realize that of the $100 billion spent in 1984 for R & D most went for military research which is not relevant to strengthening the basic science of our country. Only $8 billion found its way to the universities. And that is not commensurate with the demands being placed on the universities. Some reallocation of R & D funds, even if total federal spending is reduced, would still provide plenty of money for what needs to be done.

University research is so important for two reasons: it provides the improvement of our store of basic knowledge on which everything will be built in the future, and the universities are the source of all of our scientists and engineers for the future. In essence, we're saying we ought to put more into the seed on which we're going to depend for the future. There's no reason why this can't be done if it's simply recognized. I think the Congress will be sympathetic to this.

It is also clear that in some areas we may not be able to accomplish all the things that would be in the national interest. Under these circumstances, as we point out in our report, universities should be prepared to make hard choices, to operate within the levels of external support available. This will require trade-offs among faculties, facilities and programs which are necessary to maintain their excellence and vitality.

VOLUNTEERS SOUGHT FOR RESEARCH ON PANIC ATTACKS

STANFORD—

People who suffer frequent attacks of panic or anxiety are being sought as volunteers for a study by researchers in the Department of Psychiatry and Behavioral Sciences at the Stanford University School of Medicine.

The researchers are attempting to measure the effects of panic attacks on heart rates and other physiological changes and to determine the value of certain treatments for panic.

Volunteers will be asked to wear small computers that measure physical activity and heart rate and to write in a diary when they think they have experienced an attack of panic or anxiety.

They will have physical examinations as well as diagnostic interviews to determine if they are acceptable for the study. All treatments include medication.

"The long-term purpose is to develop better and safer treatments," said Dr. C. Barr Taylor, associate professor of psychiatry.

Anyone interested in participating in the study should telephone (415) 723-7240.

FAMILY HISTORY OF APNEA MAY INDICATE RISK OF SUDDEN INFANT DEATH SYNDROME

STANFORD—

Sudden Infant Death Syndrome (SIDS) may be a particular risk for babies who inherit a physical trait that probably has caused breathing problems in generations of their relatives, according to a study by researchers at Stanford University Medical Center and the University of California, San Francisco.

The physical trait is a small upper airway, usually behind the base of the tongue. It was found in six infants hospitalized after suffering "near-miss" SIDS episodes—and it was found in several of their relatives.

Four siblings of the six infants had died of SIDS, but they were not examined for small upper airways.

"We found out that in each generation on one side of the family, we had someone who obviously had a breathing problem and at the same time an abnormality of the upper airway," said Dr. Christian Guilleminault, associate director of the Stanford Sleep Disorders Clinic and professor of psychiatry in the School of Medicine.

Guilleminault, the lead researcher on the study, discussed the findings in an interview. The research was first reported in the Feb. 22 issue of *The Lancet*, British medical magazine.

The six infants in the study came from five families. In all of the families, one or two infants had died of SIDS and another child had apnea, or two infants had apnea. Apnea is an interruption of breathing during sleep that lasts a minimum of 10 seconds and is sometimes life-threatening.

Guilleminault emphasized that not much is known about SIDS, which claims 8,000 lives a year in the United States, and he said it probably has multiple causes. The research concentrated on a subgroup of SIDS patients, he said, and the findings probably do not extend to all SIDS patients.

However, the researchers did conclude that a small upper airway is "a risk factor for breathing impairment during sleep. It seems to be a familial feature, and should be suspected when sleep apneas in infants continue beyond the age of 10 months."

During sleep, Guilleminault said, there is a decrease in the size of the airway. That decrease, he added, "is much more pronounced in REM (rapid eye movement) sleep, when there is a lot of loss of muscle tone, particularly in the muscle of the tongue."

Infants have small windpipes simply because of their small size, he said, and those who inherit the small upper airway are particularly susceptible to breathing difficulties during sleep.

2-2-2 Adults with the same family characteristic may have breathing problems during sleep throughout their lives, particularly when they have colds or if there is some other complicating factor such as extra weight (fatty tissue can reduce the size of the already small airway).

Guilleminault said that in years of studying adults with sleep apnea he had heard references to children in their families who had died of SIDS. He and his colleagues decided to start the research with infants after discovering several cases of near-miss SIDS events, "meaning they were picked up by the parents at a time they were supposed to be asleep and they were found to be blue or very pale and not breathing."

Besides Guilleminault, the researchers were Drs. Nelson Powell and Robert Riley, who have DDS degrees as well as MDs, and Dr. Gregory Heldt, a pediatrician from the University of California, San Francisco.

They studied the six infants who had suffered near-miss SIDS episodes, their four living siblings, 10 parents and eight grandparents.

"We did a complex study of the families," Guilleminault said. "We used X rays and sometimes volume CT scans to look at the upper airways. We also monitored the breathing patterns, particularly when they were asleep."

They found a distinct connection between the small airway and breathing problems and they traced that connection through three generations.

"Each time we found it in the same direction," Guilleminault said. "If it was the father who had the problem, it showed up in one of the paternal grandparents."

Those who had breathing problems usually had other symptoms associated with sleep apnea. For example, many were heavy snorers and some of the grandparents tended to have excessive daytime sleepiness—which often accompanies a high level of respiratory disturbance during sleep.

Guilleminault also noted that a small upper airway is usually accompanied by a distinguishing facial characteristic: a small or discreetly recessive chin.

That also usually means a malocclusion, or improper alignment of the teeth, Guilleminault said. He noted that dentists have known for years that malocclusion runs in families, but "dentists are interested in teeth, not necessarily in the windpipe."

He added: "We are saying there is a subgroup of individuals who have a tendency to have an anatomical abnormality that may run in families that has an impact on the size of their windpipe."

However, he emphasized that not every child in a family inherits the same anatomical characteristics and a history of sleep apnea in a family does not necessarily mean an infant has a small airway or is at greater risk of SIDS.

Surgery can ease the problems of infants who do have small airways. All six infants in the study eventually had tonsillectomies and two underwent resectioning of the lateral walls of the soft palate to enlarge their airways. None has sleep apnea now, but two are intermittent snorers who snore continuously when they have upper airway infections.

Doctors also warned the parents that apnea could reappear if the children gain excessive weight or in boys when they reach puberty, which brings thickening of the mucosa in the pharynx.

STANFORD MEDICAL STUDENTS FARE WELL IN INTERNSHIP MATCHING

STANFORD—

Out of a graduating class of 58 students at Stanford University Medical School this year, 65 percent were matched to their first choice of internship, and 84 percent obtained one of their first three choices, said Dr. Roy Maffly, associate dean of student affairs.

The 38 graduates who got their first choice hospital represents an increase over the last five years, which averaged 53 percent. And the 11 graduates who got one of their top three hospital choices represents an increase over the last five years, which averaged 72 percent, said Maffly in a report on the annual internship matching.

Seventy-two percent of the graduates will intern at university medical centers, Maffly continued. Of those, 21 percent will remain at Stanford and 17 percent will go to hospitals within the University of California system. Three percent will go to hospitals affiliated with Harvard Medical School.

"These are very satisfying results," Maffly commented. "They must reflect on the caliber of the graduating students, and they indicate that Stanford's clinical program must be well thought of."

The types of internships pursued by the graduates for the most part mirror 10 year averages. About 50 percent chose internships in medicine, 16 percent chose surgery and seven percent chose pediatrics. Obstetrics and gynecology and emergency medicine internships are on the rise in popularity, Maffly's report stated, with 10 percent of the students choosing the former and five percent choosing the latter. Family practice internships, on the other hand, are on the decline, with only three percent of the students choosing them.

As in past years, students' career choices differ somewhat from their internship choices. About 30 percent would like to practice internal medicine. Another 16 percent are going for surgery, while a high of 13 percent are aiming towards anesthesiology. Obstetrics and gynecology is the career choice of 12 percent of the graduates; pediatrics is the goal of seven percent. Only five percent of the graduating students listed research as their career goal.

STANFORD MEDICAL SCHOOL STUDENTS OFFERED DIVERSE ACADEMIC OPPORTUNITIES

STANFORD—

The adage that medical students "eat, breathe and sleep medicine" is losing ground at Stanford University Medical School where, with the encouragement of administrators and faculty, more students each year round out their curriculum with nonmedical courses and activities.

In 1986, 65 percent of the medical students decided to stay at Stanford for longer than the standard four-year medical education. This tops 55 percent of the students who chose to prolong their medical education in 1985, and it signals an increasingly popular trend.

"There is considerable feeling that medical education is too narrow, too technical and that there is a lack of balance with nonmedical knowledge," said Dr. John Steward, associate dean for student affairs. Stanford tries to counter this image by encouraging its students to spread out their medical education over a longer period of time so they can include courses in the humanities, pursue hobbies and do research.

Stanford is unique in its stance, Steward explained. Admittedly, this year's quarterly tuition of $4,110 is none too cheap, but students are only charged for 13 quarters. If they choose to stay in school longer, it's at no additional cost.

The flexibility of the curriculum is also rare among medical schools, intentionally so to encourage students to take a broader range of courses, Steward said. In fact, the medical school's mission states that it will provide an educational environment that encourages "intellectual diversity."

Some students complain that the return in 1984 to a required curriculum for the preclinical years decreases that flexibility, but Steward disagrees. "Students don't have to complete their preclinical courses in two years. They can take as long as they want."

Stanford is one of a small group of medical schools in the country that is located on a university campus. In fact, in deciding to move the medical school from San Francisco in 1959, giving medical students an opportunity for "a broader focus" was one of the main considerations, he said.

The emphasis on the opportunity for a broader focus is a major consideration for many of the students who come to Stanford. It's one of the main points that third-year student Danny Sze stresses when, as a member of the admissions panel, he talks to candidates.

"Stanford is really well suited for people who like learning and who aren't yet willing to shut any academic doors," he said. Sze, who's earning a Ph.D. in biophysics as well as an M.D., has delved into oil painting, windsurfing, jazz dance and ballet and photography, just to name a few, since he's been at Stanford. In the past year he's made all the furniture for his apartment, has played cello with the local orchestra and does some graphic design on the side. "If you know how to manage your time effficiently, you can do a lot of nonmedical things," he added.

5-27-86 more

Allen Efron, another third-year student, came to Stanford with the intention of getting through in four years. He admits he was a little scared when he considered deviating from his initial plan and taking another year, but did it anyway. In addition to taking computer science and French courses at Stanford, he spent a quarter at Oxford University studying the philosophy of the mind and brain. Now that he's back, he'd like to try his hand at creative writing. "Students should exploit as many of the resources here as possible," he said. Premed students have to pass up a lot of courses just to get those they need to get into medical school, he said. At Stanford, he feels he has the opportunity to make up for lost time.

Second-year student Marlene Sturm doesn't need to make up for lost time, yet she treasures the flexibility at Stanford for another reason. A comparative literature major in college, she continues to take humanities courses and is an accomplished pianist. "The nonmedical courses give me a sense of continuity," she said. "In medical school people tend to change quite a bit." Pursuing a few of her nonmedical interests, "helps me feel like I'm still the same person."

Sturm has had a chance to share her musical skills with her classmates at a monthly humanities group, where students take turns making presentations that have featured, for example, literature, poetry, art, ethical issues and in Sturm's case, piano pieces by Chopin. The group has drawn as many as 40-50 students, said Kathy Bradley, who organized it when she came to Stanford nearly three years ago. "I felt isolated, so one day I put notes describing what I wanted to do in all the students' mailboxes. About 15 showed up at my house at the designated time. And it's continued since.

"Medical school, especially the preclinical years, is downright boring and intellectually unstimulating," she said. "The basic work in medicine is humanities. Medicine doesn't have a cure for everything, so physicians have to be able to bring much more to their patients."

"The main thing physicians bring to their practice is themselves," agreed Lisa Smith, a fifth-year student. "It's important not to become too narrowly focused. You have a lot more to offer patients if you haven't excluded everything but medicine."

But the increasing cost of medical education, combined with the dwindling funds available for financial aid, is causing some medical students to make some exclusions, to pass up alternative routes for the quickest way through medical school so they can start earning an income to pay off their debt, said Steven Freedman, who started medical school six years ago. "I'm already $55,000 in debt, and I don't think I ever want to practice clinical medicine," he said. But if his current project is successful, he may not need to. Freedman, whose Stanford education has included computer science and communications as well as medical classes, has helped found a company called *Dynatext*. Still in its infancy, the company is developing a computerized medical library, in a sense. Rather than go from one book to the next for information, users can call up information from an array of standard medical texts and journals all on the same screen.

"Dr. Steward once said to me, 'I don't think you would have finished medical school somewhere else', " Freedman recalled. "Without the alternatives, I probably wouldn't have. Nor did I have any notion that this would be what I ended up doing."

"Stanford," Sturm summed up, "is open-minded about how to educate oneself. It lets you make most of those decisions."

SCIENTISTS REPORT NEW MECHANISM BY WHICH AIDS VIRUS CAUSES CELL DEATH

STANFORD—

A new finding about how the virus that causes acquired immune deficiency syndrome (AIDS) can kill cells in the immune system has been reported by a group of scientists from Stanford University School of Medicine and three other institutions.

The finding helps explain how the virus profoundly cripples AIDS patients' defenses against disease and cancer, said Dr. Edgar Engleman, associate professor of pathology and medicine and director of the Stanford Blood Center.

The discovery is "*not* a therapeutic breakthrough," Engleman stressed, but it could open up new approaches toward developing drugs or vaccines to block AIDS.

The new finding shows that cells infected with the AIDS virus fuse with healthy, uninfected cells, forming giant cell agglomerates which produce large quantities of virus and then die, Engleman explained.

The giant cells enlarge by fusing exclusively with helper T lymphocytes, white blood cells that orchestrate the body's defenses.

The disappearance of helper cells into dying giant cells could explain the collapse of immune defenses that is the hallmark of AIDS, he said.

"If you lose the helper cells, you lose the immune defenses, because without helper cells most of the immune system cannot be activated," he explained.

Engleman suggested that it could be valuable to look for drugs or vaccines that block the fusion process. "Right now, most of the experimental agents being tested against AIDS are aimed at blocking viral replication," he explained. "This provides a whole new avenue whereby we can try to prevent the virus from destroying the immune system.

"We should be trying to attack the virus at every point in its life cycle," he added. "It's important to test agents that interrupt viral replication, but we should also explore the use of agents that interfere with AIDS virus-induced cell fusion," he suggested.

The report on the giant cells will be published in the May 30 issue of *Science* magazine. Besides Engleman, co-authors on the article include Dr. Jeffrey Lifson, associate investigator at the Palo Alto Veterans Administration Medical Center, Dr. Gregory Reyes, a senior scientist at Gene Labs, Inc., of San Carlos, Dr. Michael McGrath, assistant professor of medicine at the University of California, San Francisco, and Dr. Barry Stein, research associate in Engleman's lab.

The work was funded by grants from the National Institutes of Health, the Medical Research Service of the Veterans Administration, the California State AIDS Task Force, and by fellowships from the Damon Runyon-Walter Winchell Cancer Fund.

Although the research was carried out on cell cultures in the laboratory, Engleman believes that the same process of giant cell formation, leading to helper T cell depletion and subsequent immune collapse, occurs in AIDS patients.

"You do see giant cells in the lymphoid organs of AIDS patients," he said. "I don't think there's much doubt that this process is also going on in AIDS patients."

Most research has concentrated on other ways to explain cell death caused by the AIDS virus. The most popular hypothesis has been that the virus commandeers its host cell to produce new viruses, ultimately working the host cell to death in the process.

"We are proposing a relatively new concept," Engleman noted, but added that "we are not claiming that this is the only way the AIDS virus kills cells."

Engleman said some other viruses are known to cause giant cell formation. But what sets this disease apart is the virus' cell specificity; the AIDS virus-infected giant cells engulf only helper T cells.

The researchers found that the basis for this specificity is a cell surface protein called CD4, which is found primarily on helper T cells. The virus-infected cells appear to use this surface molecule to latch onto uninfected helper cells. Other research suggests that the free-floating AIDS virus uses the CD4 protein to enter and infect cells.

"Not only is this a mechanism whereby the virus spreads," Engleman said, "but more fundamentally it's a mechanism whereby a single AIDS virus-infected cell can sop up many uninfected cells and kill them."

Engleman noted that in previous research he and his colleagues demonstrated that the CD4 molecule is essential to helper T cell function—without it, the normal immunological activity of these cells is blocked.

So, in looking for drugs or vaccines that block the cell fusion process, it would be crucial not to block the normal immune functions of the CD4 molecule, he cautioned. His research group is conducting preliminary studies of agents that could potentially fit these requirements.

VOLUNTEERS STILL SOUGHT FOR CHOLESTEROL STUDY

STANFORD—

The Stanford Center for Research in Disease Prevention is looking for additional volunteers for a cholesterol study.

Dr. Robert Superko, medical director of the Lipid Research Clinic at the Medical Center, says the project is attempting to learn whether colestipol, a drug widely used in lowering high cholesterol, is also effective in people with moderate levels of fat in their blood.

Superko said volunteers should know that they have total cholesterol levels between 220 and 280 mg/dl, a level normally treated by diet, not medication. There will be three groups of participants who will take colestipol in doses lower than those normally prescribed. A fourth group will take a placebo, an inert substance that tastes like the medicine.

Participants' blood cholesterol levels will be measured at regular intervals for the 16 weeks of drug therapy, Superko said, and blood pressure and other medical data will be made available to volunteers without charge.

An initial group of volunteers were recruited several months ago and are continuing with the study, Superko said.

Persons interested in volunteering or attending an informational meeting should contact Paula or Pamela at (415) 725-5038 after 1 p.m. on weekdays.

$70 MILLION PACKARD PLEDGE FOR NEW CHILDREN'S MEDICAL CENTER AT STANFORD

STANFORD—

Lucile and David Packard have pledged $70 million to finance construction of a comprehensive new children's medical center by Stanford University and Children's Hospital at Stanford.

The gift encompasses a previous Packard pledge of $20 million for the project, making it the largest commitment from a private donor in Stanford's history, said University President Donald Kennedy Tuesday, May 13.

In a joint statement, Kennedy, Dr. Lawrence G. Crowley, board chairman of the New Children's Hospital at Stanford, and Charles Anderson, vice board chairman of Children's Hospital at Stanford, said:

"We're grateful to Lucile and David Packard for their generosity. It renders possible a magnificent contribution to human welfare—and to children especially."

Lucile Packard, a Stanford alumna, has been active in the Children's Hospital at Stanford for many years and now is chairman of its board. She is also vice chairman of the new board planning the project. David Packard, a Stanford alumnus, is chairman of the board of the Hewlett-Packard Co.

The Packard pledge includes $40 million to cover part of the design, planning, construction, and equipment costs of the new children's hospital; $22 million toward Stanford University Hospital's modernization project, including perinatal facilities; and $8 million for modernizing pediatric academic space of the School of Medicine.

Under the terms of the pledge, the University will pursue a $20 million development program for the new children's hospital as part of the current medical center fund-raising agenda. The total cost of the facility is estimated in excess of $60 million.

"The gift," Kennedy said "will enable the University to embark on a partnership with the Children's Hospital at Stanford in establishing one of the foremost comprehensive centers for pediatric care, research, and training in the country.

"It's in pediatrics that medicine faces its most exciting challenges. Each child born with a birth defect or incurable disease exemplifies the need for further knowledge. A better understanding of the causes of illness, better ways of detection, treatment, and prevention will result in dramatic changes in the quality of life."

These improvements span entire lifetimes, Kennedy added. "That is why investments in the health of children are very powerful."

Beyond the new facility, Kennedy said, the gifts complement University efforts to modernize Stanford hospital and academic research space for the Stanford University School of Medicine.

"Related to the new thrust will be the medical school's new Center for Molecular and Genetic Medicine," said David Korn, vice president and dean of the medical school. "Nowhere are the applications of the new genetic medicine more critical or promising than in the field of childhood disease."

Planning of the new 125-bed hospital is directed by a new 20-member board of directors chaired by Crowley, who is a former Stanford vice president for medical affairs. Twelve of its members are appointed by the Children's Hospital at Stanford and eight by the University. The project director is Langston Trigg Jr.

The facility, being designed by the San Francisco architectural firm of Anshen and Allen, will be attached to Stanford University Hospital's new addition scheduled for opening in 1987. Construction of the new children's hospital will begin shortly after, with completion expected in early 1989.

5-13-86

-more-

The New Children's Hospital at Stanford will be an integral part of the Stanford University Medical Center, but its governing and management structure will be separate and independent, according to agreements approved by the University Board of Trustees and Children's Hospital at Stanford.

The new facility will be the medical school's principal hospital for clinical practice, research, and teaching relating to children's medical and health care.

Stanford and Children's Hospital have been operating their complementary pediatric programs from separate locations for many years under the medical direction of the Department of Pediatrics.

The new, three-story building will consolidate the pediatric and psychosomatic beds at Children's and the pediatric acute, pediatric intensive, and neonatal intensive care beds at Stanford.

The new hospital will house the Stanford Children's Ambulatory Care Center, which provides 27 separate clinical services. It will also include a compromised host unit, a day hospital, a 150-seat auditorium, cafeteria, and support services ranging from clinical laboratories and physical therapy to diagnostic radiology.

Stanford hospital's well-baby nursery and about 50 medical-surgical beds for mothers will be closely linked to the labor and delivery suites located in the new children's hospital.

By placing these units adjacent to each other the two hospitals will be able to provide an important new perinatal service for mothers and children. "The bringing of child and mother together is an important concept in the new facility," Crowley said.

"The Packard gift gives us an opportunity to put together all of these services in a very thoughtfully designed modern, efficient facility which will become a major center for pediatric care in the region and beyond," said Dr. Irving Schulman, chairman of the Department of Pediatrics and chief of staff at Children's Hospital.

• • •

Packard was born in Pueblo, Colo., in 1912. He attended Centennial High School in Pueblo, where he was an exceptional student and athlete. He attended Stanford University, receiving a bachelor of arts degree in 1934, and a master's degree in electrical engineering in 1939. After a brief stint with General Electric Co. in Schenectady, N.Y., he returned to Palo Alto and joined William Hewlett on a research project at the University.

The two friends in 1939 formed the Hewlett-Packard Co. Their workshop was a small garage in Palo Alto. One of their early devices was a new type of audio oscillator, based on a design by Hewlett. It represented a significant contribution to the field of electronic measurement. Today Hewlett-Packard is a worldwide organization with manufacturing plants in the United States and 12 countries in Europe and Asia. The company manufactures computers and electronic instruments and employs 80,000 people worldwide.

Packard was a member of the Stanford Board of Trustees and played a key role in the decisions that resulted in the construction of the Stanford University Medical Center and the move of the medical school from San Francisco to the campus.

Packard has served as deputy secretary of defense, and on numerous presidential task forces and commissions.

Mrs. Packard, the former Lucile Salter of San Francisco, graduated from Stanford in 1935. She has been a member of the board of directors of Children's Hospital since 1967 and has chaired the board since 1983. She has served as board president of the Children's Health Council and on the boards of Castilleja School and the San Francisco Symphony.

In addition to her work on committees and fund-raising drives on behalf of Children's Hospital, Mrs. Packard has been one of the original board members of the New Children's Hospital at Stanford planning the new facility. She has been the vice chairman of that board for the past three years.

The Packards have four children and nine grandchildren.

PAIN IS UNRELIABLE FOR DIAGNOSING CORONARY ARTERY DISEASE

STANFORD—

Severity of angina—pain caused by narrowed coronary blood vessels—does not reliably reflect the severity of a patient's heart disease, a 10-year Veterans Administration study of 686 cardiac patients has revealed.

The finding is important because many physicians use the severity of a patient's symptoms, often without further testing, to evaluate the seriousness of coronary artery disease, according to Dr. Herbert Hultgren, the study's medical co-chairman, and professor of medicine at Stanford University School of Medicine.

"Physicians should no longer assume that coronary disease is mild just because a patient's symptoms are not severe," Hultgren said.

"We have found that some patients with very mild symptoms may have severe underlying heart disease that places them at high risk for a heart attack or sudden death," he said. "Others with severe angina may have only mild disease," he pointed out.

The new findings suggest that any heart patient with angina should undergo exercise treadmill and nuclear imaging tests for further diagnostic evaluation to evaluate their risk "profile," Hultgren added. "Testing should not be delayed, even in patients with mild symptoms," he stressed.

During exercise testing, a patient walks on a treadmill or pedals a cycle while his heart rate, blood pressure and electrocardiogram are monitored. Nuclear imaging is a method of using small amounts of radioactive tracers to obtain pictures of the blood flow to the heart muscle.

The VA study revealed that nine percent of patients with mild symptoms of angina actually had left main coronary artery disease, a high risk form of heart disease, while 56 percent had narrowing of the three main blood vessels in the heart, also considered serious.

Altogether, 34 percent of the patients with mild symptoms were considered to be at high risk for subsequent heart attack or death. That figure is only slightly lower than the 43 percent of patients considered high risk in the group with severe angina.

The Veterans Administration Cooperative Study was initiated in 1970. Patients joined the study from 1972 to 1974 from the Palo Alto Veterans Administration Medical Center and 12 other VA hospitals throughout the country, Hultgren said.

A progress report on the study, which will follow patients for a total of 15 years, was recently published in a series of articles in the November 1985-April 1986 issues of the journal *Progress in Cardiovascular Diseases*.

more

5/8/86

2-2-2

In earlier reports, the VA study also concluded that certain types of heart patients are best treated with bypass surgery, whereas postponing surgery as long as possible should be recommended for most other patients, Hultgren said.

In bypass surgery, a segment of vein is removed from the patient's leg and sewn into the heart to form a bypass channel in which blood can flow around the blocked artery. The operation is one of the most commonly performed surgical procedures. Its national cost is estimated at over $3 billion, according to the American Heart Association.

The patients who benefit most from bypass surgery are those with narrowing of the left main coronary artery. Eighty-eight percent of a group of such patients who had surgery during the VA study survived at least 42 months. In contrast, the 42-month survival rate was only 65 percent among a group of similar patients who were treated with drugs but did not undergo bypass surgery.

"For patients with left main coronary artery disease and three-vessel disease with abnormal left ventricular function, we would therefore recommend surgery to improve survival, even if patients have only mild angina symptoms," Hultgren said.

"But other heart patients can generally be treated without surgery with no adverse effects on survival," he added.

With this in mind, surgery should be postponed as long as possible in low-risk heart patients, idence from the VA study suggests. This is because the operation's benefits begin to dwindle after about a decade, as new blockages form in the bypass grafts.

"We saw improved survival in the surgery group out to about eight to 10 years," Hultgren noted. "But after 10 years, there was a rapid fall-off due to late closure of the grafts.

"Our recommendation, therefore, is to not operate too soon to relieve symptoms in low-risk patients because 10 years down the pike, they may need a new operation," he said.

HOSPITAL'S PACKAGED, FLAT RATE COMPONENT REACHES 10 PERCENT

STANFORD—

About 10 percent of Stanford University Hospital's total revenue is now coming from health plans that have negotiated packaged discount or flat daily rates, said David I. Sakai, director of finance.

Sakai said nearly all of the largest health insurance carriers have recently requested contract proposals from the hospital for discounted or per diem payment arrangements for their newly formed health maintenance organizations (HMOs) or preferred provider organizations (PPOs), which afford lower premium rates for companies purchasing health plans for employees.

"It is becoming apparent that the full-charge portion of our business is rapidly converting to PPO/HMO-based business at significantly discounted rates," Sakai said recently.

The finance director said the hospital currently has contracts with eight separate companies offering PPO or HMO arrangements. Active negotiations are under way with at least seven other plans.

"This volume is especially significant when you consider that three years ago PPOs and HMOs represented virtually zero percent of our volume," Sakai added.

Generally, HMOs require that enrollees go to specific physicians or medical groups to receive total care. Services are prepaid with only a modest charge, typically less than $10 a visit, for physician services. Physicians agree to send their patients to a specific hospital at predetermined rates.

The rates are less than the published rates, an arrangement made feasible because of the volume of patients and the relative ease in processing paperwork for a large number of patients under the same plan. Costs to employees are usually significantly less than plans which allow free choice of physicians and hospitals.

PPOs allow the patient to choose virtually any physician, medical clinic or hospital each time service is needed, but PPOs offer the patient a financial incentive for choosing services from providers who have agreed to participate in the discount plan.

While details of individual contracts are confidential, Sakai noted that gross patient revenues in the current fiscal year are expected to be $285 million.

Sakai detailed the current status of contracts and negotiations:

The three largest contracts, representing approximately one third of all PPO/HMO volume at SUH, are Blue Cross Prudent Buyer Plan, Blue Shield Preferred Plan and Blue Cross' TakeCare Plan.

Blue Cross Prudent Buyer and Blue Shield Preferred are both PPOs open to participation by all members of the medical staff. TakeCare is an HMO, and most patients coming to SUH under this plan come from Palo Alto Medical Clinic.

A PPO open to the entire staff includes Metropolitan Life Insurance Co.'s MetElect Plan. Aetna Life Insurance Co. has a PPO contract with SUH and for physician services with Palo Alto Medical Clinic.

Other HMOs sending patients to the hospital include Maxicare, which is provided through the Stanford University Clinic-sponsored Stanford Medical Group, and Rockridge/Health America Plan through the Midpeninsula Health Service.

Also, Stanford recently concluded PPO-based referral arrangements with Health Pace and AvMed, which are subsidiaries of National Medical Enterprises.

MICROBIOLOGIST RECEIVES MOLECULAR PARASITOLOGY AWARD

STANFORD—

Dr. John Boothroyd, assistant professor of medical microbiology at Stanford University School of Medicine, has received one of two Burroughs Wellcome Molecular Parasitology Awards for 1986.

The award provides Boothroyd with $250,000 over a five-year period. Boothroyd's selection "is a signal of honor and conveys the importance of the teaching and training activities of his molecular parasitology program," said the advisory committee of the Burroughs Wellcome Fund.

Boothroyd's work focuses on *Trypanosoma brucei*, single-celled parasites that enter the bloodstream through the bite of the tsetse fly. The organisms have the unusual ability of eluding the protective forces of their host's immune system. Like criminals with a repertoire of "aliases," they repeatedly switch the make-up of their protein coats, assuming a new disguise to stay one step ahead of the host's immune response.

Boothroyd is studying the parasite at the molecular level to learn more about how it evades the body's immune system. The knowledge could have broad implications for understanding infectious disease at the molecular level. Other organisms, including those that cause gonorrhea and acquired immune deficiency syndrome, can also elude the immune defenses.

The work could also lead to an effective vaccine or drug against sleeping sickness, a disease that causes thousands of deaths annually on the African continent.

The second award went to Dr. Jeffrey Ravetch at Memorial Sloan-Kettering Cancer Center.

Boothroyd, 31, has been a member of the Stanford faculty since 1982. He received a special fellowship award from the Burroughs Wellcome Fund in 1984. He completed his undergraduate work at McGill University, Canada, and completed his doctorate work in molecular biology from Edinburgh University, Scotland, in 1979.

The Burroughs Wellcome Fund, located in North Carolina, established the annual awards in 1982 in recognition "of the pioneering contributions of Sir Henry Wellcome to the study of tropical medicine." The awards are intended to "stimulate the advancement of fundamental biochemical knowledge of the major pathogens responsible for devastating the health of man in developing and tropical countries."

STUDY SHOWS PANIC ATTACKS REAL, NOT IMAGINARY

STANFORD—

Most panic attacks are real and not the result of victims' imaginations, according to a study by researchers at the Department of Psychiatry of the Stanford University School of Medicine.

The study, published in the April 1986 issue of the American Journal of Psychiatry, found that 58 percent of the panic attacks reported by patients were verified by increased heart beats measured on small computers worn by the patients.

Twelve female patients with self-reported panic attacks and a control group of 12 women with no panic history were involved in the study. Similar results have been obtained since that study with a larger group of 50 male and female patients, said Dr. C. Barr Taylor, associate professor of psychiatry who was the principal investigator.

In the initial study, Taylor said, there were 33 panic attacks reported by the patients and in 19 of them heart rates were "disproportionate to the physical activity."

"That may seem like a very tedious way of finding the obvious," Taylor said, "but in fact no one has ever known whether or not you could measure panic attacks. The patients are often told by their physicians that they're making it up, that it's all in their heads."

One fringe benefit of the study, Taylor said, is knowledge that should reassure victims of panic attacks.

Although they are often terrified and have a "sense that they're going to die," he said, "they're physiologically not in any danger. The heart rate rarely goes to a level that is worrisome from a medical standpoint."

All of the patients have been equipped with Vitalog MC-2 computers, worn on belts and programmed to store data on heart beats and on eight levels of physical activity. Patients wear the computers for six days, during which they are asked to record in a diary all panic attacks or anxiety episodes.

In the study, three observers analyzed heart rate activity. The observers had no knowledge of the patients or of the panic attacks reported in their diaries. They were looking for three criteria:

- An increase of at least 30 beats a minute from surrounding 15-minute periods.
- An increased heart rate lasting at least three minutes.
- An increase accompanied by little or no physical activity.

Only when all three observers agreed on an episode of increased heart rate activity and when it occurred at the precise time noted in the patient's diary was it recorded as a definite panic attack.

One of the more significant findings of the study was that the nighttime panic attacks commonly occurred from 1:30 a.m. to 3:30 a.m., at times when hormonal shifts normallly occur in the body. The Stanford researchers are investigating that connection.

Taylor said attacks of panic or anxiety probably affect 5 to 6 percent of the entire U.S. population. "According to some studies, it's the most common psychiatric disorder," he said.

In the past, women have been considered 10 times more likely to be affected than men, but men have made up 32 percent of the total in the Stanford studies. It's possible men may be more willing to come in for studies, Taylor said.

Aside from the fact that more women are affected, "we don't really see any male-female differences," he said. "In terms of treatment outcome or medication side effects or improvement, both do equally well."

"The long-term purpose of all this is really to develop better and safer treatments," he explained. "That's one of the reasons we're so interested in the heart rate data—because the drugs we use do have some effect on the heart rate."

The Stanford research team is seeking volunteers for further study. Individuals with a history of panic or anxiety attacks are asked to telephone (415) 723-7240.

All participants will undergo thorough physical examinations and diagnostic interviews. They must meet specific criteria and can't have certain medical problems.

Researchers, in addition to Taylor, are Dr. Javaid Sheikh, Dr. W. Stewart Agras, Dr. Walton T. Roth, Juergen Margraf, Anke Ehlers, Dr. Richard J. Maddock and Dr. Denis Gossard.

FOR IMMEDIATE RELEASE
(Editors: Members of the news media are welcome to attend the lecture, "Perspectives on Public Health in Chiapas" at noon Wednesday, May 21 in room M-106 of the Stanford Medical School.)

UNIVERSITIES SIGN AGREEMENT WITH MEXICAN STATE

STANFORD—

Herbal treatments still used by descendants of the ancient Mayans and recombinant DNA techniques are part of a research agreement among Stanford, the University of California at Berkeley and a rural Mexican state.

The two Bay Area universities and the public health service of Chiapas, which borders on Guatamala, were scheduled to ratify a formal agreement during the week of May 19 which will provide for collaborative research on a variety of environmental health issues, said Dr. Elois Ann Berlin, assistant professor of Family, Community and Preventive Medicine (FCPM) at Stanford.

"Our overall goal is to develop research projects that are in keeping with the goals of the public health department in Chiapas," said Berlin.

Stanford will be involved with basic research into intestinal bacterial diseases, a major health problem in Chiapas and throughout the Third World, Berlin said. Study into that question is ongoing in the Stanford laboratory of Dr. Stanley Falkow, professor of medical microbiology, and others.

Falkow said his laboratory currently is using the high technology tools available through recombinant DNA to provide accurate and effective diagnosis of bacterial infections through molecular identification.

"We've known what the treatments for various forms of diarrheal infections should be," Falkow said. "The problem has been in each case to pinpoint the specific cause," he added. "We are hoping to develop our techniques so that they can be transferred to the public health laboratory in Chiapas."

In addition to the bacterial and viral causes of diarheal disease, various parasites prevalent in Third World nations also cause many health problems, and parasitologist Dr. Paul Basch, of Stanford, will be investigating that aspect.

At UC Berkeley, Dr. Brent Berlin, a widely recognized ethnobotanist, will be working with colleagues to collect and analyze various herbal remedies used by the Indians in that rural Mexican state in hopes of eventually determining their efficacy.

Elois Berlin said the overall collaboration will attempt to determine how cultural factors influence health and the use of medical services with the ultimate aim in Chiapas of reducing disease. She added that the state is fairly typical of rural Third World areas where infectious diseases are still the leading causes of death.

Basch, of Stanford's Division of Geographic Medicine, said the agreement is expected to be signed during a week-long visit to Stanford and UC Berkeley by three public health officials from Chiapas.

And while they're visiting Northern California, the three doctors, will present a joint lecture-seminar entitled "Perspectives on Public Health in Chiapas" at noon Wednesday, May 21 in room M-106 of the Stanford Medical School. The lecture is open to the public, said Basch, who also serves at Stanford as professor of international health in FCPM.

The three visiting officials are Dr. Julio Cesar Sanchez Farrera, state director of public health; Dr. Victor M. Jara Astorga, state deputy director; and Dr. Francisco Millan Velasco, director of public health of the second sanitary jurisdiction in Chiapas.

The visiting doctors will return a visit made last September by Basch, and both Dr. Berlins.

Elois Berlin said she hoped the agreement would provide for long-term collaboration.

STANFORD HOSPITAL MOVES EMPLOYMENT SECTION

STANFORD—

The Employment/Recruitment Section of the Stanford University Hospital Department of Personnel will move to the main personnel offices in Room E009 in the Hospital basement on Monday, May 12, Employment/Recruitment Manager Renee Wald announced this week.

For the past year and a half, the section has been housed at 750 Welch Road, in a building that includes several other Medical Center offices. It has been situated outside the main hospital for the past six years.

Wald said the move is part of the Personnel Department consolidation resulting from the recent downsizing of the Hospital.

She said several hundred prospective hospital employees visit the Welch Road offices each month.

The office telephone number is 723-6361.

MAN WHO LOST LEG TO CANCER ENCOURAGES KIDS IN CHILDREN'S HOSPITAL AT STANFORD

STANFORD—

Twenty-three-year-old Jeff Keith is living proof that childhood cancer can be overcome.

In 1984 Keith ran 3,350 miles across America, after having lost a leg to bone cancer at the age of 12. He visited Children's Hospital at Stanford May 3 to encourage children there struggling with disease.

Jogging on his leg for eight-and-a-half months hurt a bit, "but you learn to suppress the pain," he said. "I lost 45 pounds and ran through 42 pairs of running shoes. Just running was hard, and that's what made me feel pretty normal," Keith said.

One purpose of his run across the United States was to increase the awareness that people who are "physically challenged" --rather than handicapped-- can participate in sports.

Keith is currently working on an MBA at the University of Southern California, but his dedication to helping others in their personal fight against cancer keeps him traveling once a week to hospitals and fund-raising events. His trip to the Bay Area was sponsored by the Golden State Moving Co. and the American Cancer Society of Santa Clara County.

Keith's experience with cancer at an early age makes it easier for him to talk to children with cancer, he said. Doctors were first alerted to his cancer after a knee X-ray, taken for an ice hockey injury, revealed a shadow in the bone just below his knee. A short time later his leg was amputated six inches above the knee to prevent the cancer from spreading.

Amputation is a common treatment for osteogenic sarcoma, Keith's type of bone cancer, which is usually found in the pre-teen or teenage years --"just when you are feeling sort of indestructible and planning great things for yourself"-- said Dr. Michael Amylon, assistant professor of pediatrics.

Keith's parents pushed him into going skiing just six weeks after his operation, Keith wearing a wig because he had lost all his hair. "I fell down for three days straight," wig and hat flying in different directions, Keith recalled. Still, skiing eventually became "everything I looked forward to," he said.

5-6-86

-more-

For children, "normal activities are important in sustaining that drive and will to live," Amylon said. Also, having a role model can have a tremendously positive impact on a child, he emphasized. "It is helpful to the parents as well," he noted.

At Children's Hospital, several of the children's balding heads were evidence of their difficult battle: loss of hair is only one of many side effects of cancer treatments. Both the treatments and diagnostic techniques for cancer are very unpleasant to undergo, Amylon said. "But the worst thing is the psychological impact on the child and the family," he pointed out.

In children, initial treatments are very aggressive because the intent is almost always curative, Amylon said. With adults "oftentimes the approach is to keep someone comfortable for as long as possible, but that is almost never our approach with pediatrics," he said.

About 15 years ago all types of cancer were considered incurable, Amylon said. Now, however, some cancers such as leukemia have cure rates of up to 95 percent. Treatments for cancer usually last from one to three years with a five- to eight-year risk of re-occurrence, Amylon said.

Children's development can't be put on hold for two or three years, Amylon said. "Children need to continue to grow, develop, interact with people, and socialize. So we try hard to get them back into the normal stream of things as much as we can and as soon as we can," he said.

Children's Hospital at Stanford is oriented to meet the special needs of children and their families needing long-term contact with a hospital. Some special programs include a summer camp and skiing program.

Generally, children "naturally" tolerate the process of treatment, better than adults, both physically and emotionally, Amylon said. "They see it sort of as part of life; this is what life has dealt them, they don't have any other choice."

Because of past experiences, "I don't go near hospitals" except to visit patients, Keith said. But, noting the amicable atmosphere of Children's Hospital, he said, "I wish I had had something like this when I was ill."

HOMOSEXUALITY AFFECTS CURE RATES AMONG HODGKIN'S DISEASE PATIENTS

STANFORD—

Homosexuality may play a complicating role in patients being treated for Hodgkin's disease, a highly curable cancer of the lymph nodes, a Stanford study has shown.

Of 19 gay men treated for Hodgkin's disease, nearly half contracted diseases related to Acquired Immune Deficiency Syndrome (AIDS), the researchers found.

What's more, those men who contracted AIDS-related diseases died within six months of the diagnoses, said Dr. Sonja Schoeppel, who led the study.

These results differ drastically from those of nonhomosexual patients treated for Hodgkin's disease. Only three percent of the patients—all of whom have repeatedly undergone therapy and therefore are most susceptible—contract AIDS-related diseases. As many as 80-90 percent of the patients treated are cured.

Schoeppel, a senior resident in the division of radiation therapy, will present the results of the study, "Hodgkin's Disease in Homosexual Men: the San Francisco Bay Area Experience," at the American Society of Clinical Oncology meeting in Los Angeles on May 6.

"Homosexual men with Hodgkin's disease are at much higher risk of getting AIDS-related diseases than other Hodgkin's patients," Schoeppel said.

The researchers do not know the precise link between the two conditions, she explained. Hodgkin's disease and AIDS-related diseases, Kaposi's Sarcoma and opportunistic infections, have similar symptoms including enlarged lymph nodes, weight loss, fever, fatigue and night sweats. Treatment for Hodgkin's disease, which includes radiation and chemotherapy, suppresses the body's protective immune system. If the immune systems in patients at high risk for AIDS are already compromised, the combined effects may allow the AIDS-related diseases to invade the body.

"We're looking for ways to predict whether a patient is likely to get AIDS-related diseases," Schoeppel said. "We could then alter Hodgkin's treatment to be as effective without suppressing the immune system as much."

In the meantime, homosexual patients diagnosed with Hodgkin's disease are treated according to established protocol. "After all, more than 50 percent will not get AIDS-related diseases," she said. "But if someone is a homosexual and also has Hodgkin's disease, the likelihood of getting AIDS-related diseases is greater."

The study included 19 homosexual men with Hodgkin's disease, diagnosed after the AIDS epidemic began in 1979 and treated at hospitals throughout the Bay Area. The mean age of the men was 37; they ranged from 24-57 years old.

Fourteen of the patients were diagnosed with the more advanced stage III or stage IV Hodgkin's disease. Of the 19, 13 underwent chemotherapy, four underwent radiation therapy and two received a combination of the two treatments. Eight of the patients developed the AIDS-related diseases.

STANFORD TESTS SHOW MINIMAL RADIOACTIVE CONTAMINATION OF CALIFORNIA WOMEN JUST RETURNED FROM VISIT TO KIEV AREA

STANFORD—

Two California women who were visiting Kiev, Ukrainian Soviet Socialist Republic, when the Chernobyl nuclear reactor accident occurred 70 miles away showed minimal amounts of radioactive contamination in tests at Stanford University Friday.

The test results, said Dr. Roland Finston, director of health physics and lecturer in radiology, indicate that the residents of Kiev are in little immediate danger from radioactivity — and make it clear that Americans should not be concerned about effects of the accident.

The two women are Jan Wilson, 38, of Oakland, and Canda Kinney, 37, of Redding. They joined Finston at a news conference after their examinations and said no one in Kiev seemed to be aware of the nuclear accident, which apparently occurred Saturday, April 26. They stayed in Kiev over the weekend but knew nothing of the accident until they received a telephone call from the United States on Tuesday, after they had reached Leningrad.

At the news conference, Finston described the tests performed on the women and said they had a small amount of iodine 131 in their thyroid glands, equivalent to about three millirads of radiation.

That is about the same amount of radiation that the average Bay Area resident would absorb from natural sources in two weeks, he said, and is such a "very small additional dose to their thyroid glands" that it represents virtually no health hazard.

However, he said, that amount of iodine in the systems of visitors to Kiev is enough to leave no doubt that there was a nuclear accident. "I think it's quite clear that this is of Russian origin," he said.

Near the end of the news conference, Finston and the women were joined by a third woman, Lucille Rose of San Jose. She too had just left Kiev and had come to Stanford to be tested by Finston. She was tested after the news conference and showed even lower traces of iodine 131 than Wilson and Kinney.

Finston explained that iodine 131 is "one of the prominent radioactive fission products that might escape from a reactor in an accident" and is easy to detect because it concentrates in the thyroid gland.

He used a sodium iodide crystal detector in the form of a tube about a foot long and four inches in diameter to focus on the thyroid glands of the women. It picked up the traces of iodine 131 in about two and a half minutes. Wilson then had a full body scan with a larger crystal detector that showed no radioactivity other than the iodine.

Asked what the tests on Wilson and Kinney indicated for the 2.5 million residents of Kiev, Finston said:

"If the average citizen of Kiev is represented by our sample here of the two visitors and if the release of radioactivity after they left the area was not strikingly different from what happened on Saturday and Sunday, I would say the citizens of Kiev are not at any risk either."

He added, "I think it is worth mentioning that based on this experience of two individuals 70 miles from the reactor coming back with as little iodine in their thyroids that it is quite clear that those of us in the United States need not be concerned for radioactive iodine or any other fission products from this accident."

However, he warned that there is a danger from people taking iodine supplements to ward off any possible threat. There have been reports of people in this country taking iodine for that purpose since the Chernobyl accident.

Wilson and Kinney both said they felt little concern about the effects of radiation, but decided to be checked at Stanford just to be sure.

In Kiev last weekend, they said, people were thronging the streets for bicycle races and there was no indication of any trouble.

As they were leaving Kiev and heading for the airport, however, Wilson said, "we saw a stream of black smoke off in the distance. It looked like it could have been a refinery fire. . . . We forgot about it until we were coming home in the airplane."

NEW DRUG COMBINATION FOR HODGKIN'S DISEASE MINIMIZES SIDE EFFECTS

STANFORD—

Stanford University cancer researchers have developed a new drug combination to help treat patients with Hodgkin's disease, a cancer of the lymphatic system.

The new drug regimen has fewer side effects than conventional chemotherapy—but is just as effective—when used following radiotherapy in patients with early stages of Hodgkin's disease, said Dr. Sandra Horning, assistant professor of medicine at Stanford University School of Medicine.

One of the new regimen's major benefits is that it appears to have almost no harmful effect on fertility, Horning reported Monday, May 5 at an American Society of Clinical Oncology meeting in Los Angeles.

In contrast, the most commonly used anti-Hodgkin's disease drugs cause sterility in approximately 90 percent of males and 50 percent of female patients, she said.

Hodgkin's disease, which tends to strike people who are in their 20s or 30s, is estimated to affect about 7,000 new patients each year. It is one of the most treatable cancers, with a cure rate of more than 70 percent.

It may be treated with radiation therapy alone, drugs alone, or with a combination of radiation and drugs. The most widely used drug combination is known as "MOPP," which stands for nitrogen mustard, vincristine (Oncovin), prednisone and procarbazine.

The new drug combination is called "VBM," short for vinblastine, bleomycin and methotrexate, Horning said.

Horning presented results from a Stanford study of 50 patients with early stages of Hodgkin's disease. Horning's colleagues on the study are Drs. Richard Hoppe, associate professor of radiology, and Saul Rosenberg, professor of medicine and radiology, and head of the division of oncology.

Half of the patients in the study received radiation therapy alone and half received radiation plus the VBM drug combination.

In the VBM group, 93 percent of the patients have remained disease-free compared with 78 percent of the radiotherapy group at 28 months, Horning reported, and no deaths have occurred. This compares favorably with results using radiation and MOPP, she added.

Seven of eight men tested showed no impairment of fertility, Horning reported. Ten of 10 menstruating women continued to have normal menstrual periods. There were three pregnancies in two different women who were given the new drug treatment, Horning added.

The new drug regimen's major side effect is muscle aching. Conventional Hodgkin's disease therapy causes nausea, vomiting, numbness and tingling related to drug therapy and additional side effects due to radiation therapy. In addition to infertility, increased risk of acute leukemia is a side effect of MOPP. But leukemia is not likely to develop after the VBM combination, Horning said.

Therefore, researchers would like to be able to reduce the use of MOPP and to reduce the total amount of radiation patients must receive, Horning said.

The results with VBM are "encouraging," she said.

STANFORD / KAISER-SAN FRANCISCO MEDICAL CENTERS TO PARTICIPATE IN $100 MILLION AIDS DRUG RESEARCH EFFORT

STANFORD—

Stanford University School of Medicine is one of 14 medical institutions selected for a nationwide research program to find a drug treatment for AIDS (acquired immune deficiency syndrome), federal officials announced Monday, June 30 in Washington, D.C..

The $100 million five-year study, funded by the National Institute of Allergy and Infectious Disease (NIAID), could enroll as many as 1,000 patients in the next six months, said NIAID director Dr. Anthony Fauci at a Washington press conference.

Approximately 50 patients are expected to be involved in the $8.1 million Stanford segment of the study during the first year, researchers said.

Those patients are expected to be treated in an experimental ward at Stanford University Hospital, at an AIDS Clinic to be established at the Stanford University Clinic, and with the cooperation of Kaiser-Permanente Medical Center in San Francisco, said Dr. Thomas Merigan, Becker professor of medicine and principal project investigator at Stanford.

The researchers hope to test one to two promising experimental drugs against AIDS each year of the study, said Merigan, head of Stanford's division of infectious diseases and an expert on viral diseases who pioneered early studies of interferon as an antiviral agent.

Although the primary goal is to identify an effective therapeutic strategy against AIDS, other objectives of the Stanford study are to learn more about the basic biology of the AIDS virus and its effects on the immune system.

"I am very enthusiastic about this effort," Merigan said. "These five years are going to be a critical time in which science can help bring this disease under control."

However, he cautioned that this is just a beginning—there is no drug yet proven effective against AIDS.

6-30-86

more

In a prepared statement distributed prior to the press conference, Fauci said: "Everyone in the scientific community who works in AIDS research shares the sense of urgency that is felt throughout the country, and now the world, as we face a rapidly growing public health problem, and as we see the toll AIDS is taking in the lives of men, women and children. We believe that this new effort should greatly enhance our research capabilities and bring us closer to the answers we seek."

AIDS is a deadly disease which destroys the immune system, leaving patients vulnerable to a multitude of bacterial, fungal and viral infections, and susceptible to certain kinds of cancers.

As many as 22,000 Americans have been diagnosed with the illness and government estimates are that the number will rise to 26,000 by the end of the year. One million or more people may have been exposed to the virus believed to cause the disease.

There is as yet no treatment for AIDS, which will have killed 18,000 patients by the end of this year, according to federal estimates.

The disease is spread through intimate sexual contact with an infected person, and by transfusion with contaminated blood or use of contaminated hypodermic needles. Most researchers believe the disease will only be controlled through a combination of prevention and treatment methods, Merigan said. Researchers around the world have been working feverishly to develop a vaccine to prevent the disease and drugs to control it.

The new AIDS Treatment Evaluation Units will concentrate on testing drugs that, in laboratory studies or in preliminary clinical trials, have shown potential to inhibit growth of the AIDS virus or have shown promise in bolstering the weakened immune system.

The drugs most likely to be tested in the first year of the study are ribavirin, azidothymidine, interferon alpha, foscarnet, HPA-23, and possibly dideoxycytidine, officials at the NIAID said.

Many of these drugs, such as HPA-23, act by inhibiting a crucial enzyme—reverse transcriptase—that the AIDS virus uses to reproduce itself, Merigan said. Others, such as interferon, may stimulate the immune system.

Nine of the AIDS Treatment Evaluation Units will also be testing drugs to control the opportunistic infections and cancers that develop in AIDS patients, according to the NIAID. Stanford will not be participating in that segment of the program, Merigan said.

The overall research program, he added, is designed to be flexible, so that if promising new agents are identified they can be brought into the testing phase as quickly as possible.

The initial studies will determine safe dosages and side effects, while later studies will assess long-term effects in controlled therapeutic studies of patients with AIDS as well as those with ARC (AIDS-related complex), a less severe condition caused by the same virus.

more

Merigan said that the tests will be conducted in both inpatients and outpatients by physicians and nurses who are experienced in treating AIDS.

Another Stanford faculty member who will be involved in the study is Dr. William Robinson, a professor of medicine and research scientist who has made major contributions to the understanding of hepatitis-B and AIDS-like viruses, Merigan said.

Other Stanford investigators include Dr. Terrence Blaschke, associate professor of medicine and head of the division of clinical pharmacology, Dr. Dennis McShane, clinical assistant professor of medicine, and Dr. William Lipil, clinical instructor of medicine.

Kaiser physicians who are collaborating include Dr. George Matula, consultant in infectious disease at Kaiser-San Francisco and chairman of the Northern California Permanente Medical Group's Regional Infectious Disease Committee, and Dr. Fred Hartley, assistant chief of medicine at Kaiser-San Francisco.

Scientists from the 14 research groups around the country will meet regularly and will be able to share research findings through computer links. "By tying together clinical research groups with a commitment to exchange information, it should be a strong step forward in trying to understand this illness," Matula said.

He pointed out that the number of patients involved will be limited at first but that as information is acquired, a broader base of patients may be studied. In order to get the information that is needed, patients must be carefully selected for such trials, he said. "Not all patients are good candidates for any given drug."

Kaiser-San Francisco, which treats the majority of AIDS patients seen in the northern California Kaiser system, has considerable experience in treating AIDS patients both on an inpatient and outpatient basis.

At Stanford Hospital, study patients will be treated in the Clinical Research Center, "a ward experienced in giving experimental therapy, with its own nursing personnel and separate physical setup," Merigan said.

Other institutions selected for AIDS Treatment Evaluation Units are San Francisco General Hospital, University of Southern California, University of California at Los Angeles, University of California at San Diego, University of Washington, University of Texas in Houston, University of Miami School of Medicine, Johns Hopkins Hospital in Baltimore, University of Pittsburgh, New York University, Memorial Hospital for Cancer and Allied Disease in New York, University of Rochester Medical Center, and Massachusetts General Hospital in Boston.

STANFORD MEDICAL STUDENTS RETURN TO ROOTS FOR TRAINING

STANFORD—

For the first time in nearly 30 years, Stanford medical students will have the opportunity to return to the medical school's roots for certain elective clerkships, an essential part of medical training.

"We're reopening a chapter of our history," said Dr. Robert Cutler, dean of faculty affairs and medical education at the Stanford University School of Medicine.

The clerkships will be offered at Pacific Medical Center (PMC) located on Clay and Webster Streets in San Francisco. Stanford Medical School was based there until 1959 when the university decided to move it to the Palo Alto campus.

The move at the time had generated bitterness among the alumni and resignations of faculty who refused to give up their practices in San Francisco and move to the Farm. Many of them currently are members of the PMC medical staff.

It was on Clay and Webster streets that most of the present medical alumni had been trained in the rudiments of their profession for more than half a century. The red brick building that housed the old Stanford medical school is now a parking lot in the shadow of a new PMC hospital and medical sciences building.

Medical students participate in clerkships during the last two years in medical school. They are carefully supervised by attending physicians who are constantly available to guide them. The four-week stints, both required and elective, allow students to take primary responsibility for the medical care of sick people, Cutler said.

At PMC electives will be available in the areas of transplantation medicine, intensive care, pulmonary medicine, occupational medicine and ophthalmology. One or two medical students at a time will be accepted in each of the five areas, Cutler said.

"They have traditionally had a very strong teaching program," Cutler said of PMC. "The clerkships there will supplement those available at Stanford, and they will provide students with a different view of medicine than they see here."

Stanford has also teaching affiliations with the Palo Alto Veterans Medical Center, the Santa Clara Valley Medical Center, the Kaiser-Permanente Hospital in Santa Clara and the Children's Hospital at Stanford.

NEW CHILDREN'S HOSPITAL BONE MARROW PROGRAM MEANS NEW HOPE FOR SAN JOSE BOY

PALO ALTO—

Four-year-old leukemia patient Darren Cachola of San Jose was released from Children's Hospital at Stanford June 25 with healthy new bone marrow.

Darren's successful bone marrow transplant is the first to be performed on a child at Stanford University Medical Center, which recently expanded its organ transplantation programs. The new pediatric transplant program is directed by the Division of Hematoloty/Oncology at Children's Hospital and the Pediatrics Department of Stanford University School of Medicine.

Darren's operation, performed on June 4, is his only hope of beating a rare childhood cancer called chronic myelogenous leukemia, said Dr. Michael Amylon, staff hematologist-oncologist at Children's Hospital and assistant professor of pediatrics at Stanford, who directed the transplant.

"So far everything has gone very smoothly," Amylon said.

Darren is the son of Magno and Grace Cachola of San Jose. His 10-year-old sister, Michelle, donated transplanted bone marrow, Amylon said.

Bone marrow transplantation is "the treatment of choice" for children with a variety of blood disorders besides chronic myelogenous leukemia, including aplastic anemia, immune deficiency states, and acute leukemia, said Dr. Bertil Glader, Stanford associate professor of pediatrics and chief of hematology-oncology at Children's Hospital.

The largest number of children who benefit from the procedure are those with acute lymphoblastic leukemia — the most common form of childhood cancer, Amylon said. In the United States, up to 2,000 children are diagnosed with this leukemia each year, he said.

Although about 60 percent of these children respond to standard cancer treatments, such as chemotherapy, bone marrow transplants are "the only alternative" for many of the remaining 40 percent, Amylon explained.

However, suitable donors are available for only 35 to 40 percent of these children because tissue types between the donor and host must be nearly identical. A close tissue match reduces the possibility of graft versus host disease, which occurs when donated immune cells attack host cells.

The donor is usually a brother or sister. "For every child there is a one-in-four chance that any one sibling will have the same tissue type," Amylon said.

It is extremely rare that the tissues of an unrelated person will match. But national tissue typing networks are being set up to help match unrelated people, Amylon said.

Normally, "stem" cells in the bone marrow generate blood cells, which in turn transfer oxygen from the l[illegible]s to tissues, fight against disease, and prevent bleeding. Stem cells also renew themselves to ensure an ongoing source of new blood.

-more

6-27-86

The first step in bone marrow transplantation is destruction of the body's own bone marrow — and immune system — by means of total body irradiation and chemotherapy. Then defective stem cells are replaced with healthy donated stem cells, Glader said.

When the patient's own stem cells are wiped out, there is danger of infections, bleeding, and anemia, Glader said. But the replacement procedure allows the donated cells to "engraft" or take up residence in the patient's bone marrow. In leukemic patients, it also helps eliminate cancer cells so that the disease does not return, Glader explained.

Stem cells are harvested from the donor under general anesthesia with a needle and a syringe. Bone marrow is removed from the back of the donor's hip bone and bone fragments are filtered out, Glader said.

Then, "like a blood transfusion," the marrow is put into the patient's circulatory system through a vein. The stem cells "home in" to the central cavities of bones. There, they adhere, reproduce, and produce blood, Glader explained. How they actually "know" to do this is a mystery, he said.

To shield bone marrow recipients from infection, Children's Hospital built a special suite of pressurized rooms with air filters to remove airborne dust and germs. This $200,000 facility, along with special staff training and other expenses, was funded by a $130,000 challenge grant from the Irvine Foundation and matching gifts from other donors.

Immunologic tests, radiation treatments, and bone marrow collection are performed at Stanford University Hospital.

Success rates for bone marrow transplants varies from 10 to 90 percent depending on the patient's previous exposure to toxic materials, the disease being treated for, and the similarity of tissue types being transferred, Amylon said.

Although adults can also benefit from bone marrow transplants, many cannot tolerate the toxic levels of radiation and chemotherapy needed for a successful bone marrow transplant, Amylon said.

"Kids are basically healthier; they tolerate treatment much better," he said.

Possible complications of bone marrow transplants include infections due to suppressed immune systems, cancer relapse due to an inability to kill all the old leukemia prior to transplantation, and graft versus host disease due to minute differences in individual tissue types, Amylon said.

Another rare but deadly complication is failure to engraft. But with modern conditioning therapy, such a failure is extremely unlikely if the donor and the recipient are well matched.

Until now, Children's Hospital at Stanford has referred about eight patients each year to other institutions "hundreds or thousands of miles away from their families, friends, and support structures," Amylon said. This can be a "financial, emotional, and psychological burden for the families at a time that is very difficult in any case," he said.

Although the program is currently aimed at providing a clinical service, in the future Amylon expects it to include research that will, for example, expand the use of bone marrow transplantation to patients with "less than perfectly matched donors" and to patients with inherited diseases such as sickle cell anemia, thalassemia, and inborn errors of metabolism.

Amylon also suggested that future research may one day enable doctors to replace the defective or missing genes in stem cells, rather than replacing whole stem cells.

According to Dr. Irving Schulman, chief of the Department of Pediatrics at Stanford University Medical Center and chief of staff at Children's Hospital, the new children's bone marrow transplant program will be a component of a major bone marrow transplant effort at Stanford.

SUMC OFFICE OF COMMUNICATIONS RECEIVES TOP HONORS

STANFORD—

Stanford University Medical Center's Office of Communications has received top honors for its news writing program and magazine, *Stanford Medicine*, from the Council for Advancement and Support of Education (CASE).

The office received a "gold medal" for excellence in news writing, which includes news releases that go to local and national media and articles that appear in the medical center's section of the university's weekly newspaper, *Campus Report*.

For the second time in three years, *Stanford Medicine*, published by the office three times each year, was named to the "top ten" list of university magazines nationwide. An article that appeared in the Fall 1985 issue of the magazine, "Life After Cancer," by managing editor Shirley Kraus, received a "gold medal" for best articles of the year.

The magazine was also named the "best of the west" magazine by the Association of Western Hospitals, and was awarded a silver medal from the Society of Publication Designers earlier this year.

The office is directed by Spyros Andreopoulos. Staff writers include Kraus, Ron Goben, associate director; Laura Hofstadter, science editor, Mike Goodkind, *Medical Center Report* editor and Jane Reimold, publications editor. Support staff includes Lyn Tadena, Mary-Nelson Campbell and Becky Berntson. Palo Alto graphic designer Mike Shenon provides the art direction for the magazine and Janet McNeill, director of publications at Stanford University, directs the production.

SCREENING FOR HYPERTENSION DOESN'T INCREASE ABSENTEEISM, STUDY FINDS

STANFORD—

On-the-job screening for high blood pressure does not generally cause increased absenteeism and psychosocial problems among those employees determined to be hypertensive, according to a study by researchers at the Stanford University School of Medicine.

The results of the study contradict earlier research that indicated such screening could produce major increases in illness-related absenteeism, and therefore have "critical implications" for the public health philosophy of preventive care, said Dr. Peter Rudd, associate professor of medicine.

Rudd was the principal investigator on the Stanford study, which was reported in the May 1986 issue of the *American Journal of Medicine*.

Identifying hypertension, or high blood pressure, is particularly important from a public health viewpoint, Rudd said, because it is a disease that can result in serious medical problems but has few symptoms.

However, earlier investigations had caused concern about the tradeoffs of such screening at the work site. In particular, a study of male steelworkers found that those newly labeled as hypertensive often developed some psychosocial dysfunction and had a higher degree of absenteeism.

The Stanford researchers focused directly on the issue of absenteeism and psychosocial dysfunction. They studied a heterogenous group of 5,888 workers from 11 Silicon Valley work sites and in screening found 296 with sustained hypertension—those who had blood pressure of at least 140/90 on three out of three determinations over three weeks.

Unlike the steelworkers, however, the employees in the Stanford study who were identified as hypertensive showed no significant increase in absenteeism or psychosocial problems when their records were compared to those of control subjects who were not hypertensive.

(Each hypertensive person in the study was matched with up to three control subjects on the basis of job type, work site, sex, age, race, educational level, household income and marital status.)

Rudd said one key to the Stanford study was "standardized labeling" of the individuals identified as hypertensive. "We always did it in a consistent way," he said, "since how the message is given may be as important as the message itself."

6-24-86

-more

However, there were two different ways of delivering the message. One he described as "a traditional, perhaps arousal or fear-type message in which we said effectively that 'You have high blood pressure, it may be a silent killer, you shouldn't ignore it.'

"In contrast, we had a reassurance message in which we said, 'Well, after all, blood pressure is a biological variable with a lot of difference from moment to moment in response to stress and we urge you not to overinterpret a single elevation today.' "

People who got the reassurance message, Rudd said, had significantly lower levels of sustained anxiety than those who received the traditional medical warning. They also exhibited a lower prevalence of hypertension, but the difference was of marginal statistical significance.

What was significant, he said, was the fact that participation in the study was voluntary after company-wide publicity. That resulted in a relatively low participation rate of 48 percent compared to near 100 percent for similar mandatory studies, such as that of the steelworkers.

"At one level, this (participation rate) was disappointing," Rudd said, but it may explain the difference in absenteeism changes between the Stanford study and earlier research.

"There may be reluctant participants who avoid voluntary screening but are captured by mandatory company-wide programs achieving almost 100 percent participation," he said. "Such individuals avoid the medical care system by and large."

When such individuals are forced to participate in screening and receive "unpleasant messages" about having high blood pressure, he said, "their self-image may be affected by attribution and they may take up 'sick-role' behaviors," which could translate into increased absenteeism or other psychosocial problems.

Rudd called that reasoning about reluctant participants "a provocative hypothesis," but emphasized "it is a hypothesis rather than a proven fact. From a public policy perspective, we must apparently choose between screening everyone and then dealing with some adverse reactions or screening only volunteers who minimize adverse reactions by self-selection, but then ignoring the reluctant participants with unsuspected hypertension.

"Our study offers reassurance that screening self-selected volunteers for hypertension avoids important adverse reactions which we measured. It remains an unresolved question about how optimally to approach, screen and label reluctant participants. For now, the best recommendations include explicit reassurance messages from the initial screening and close linkage with follow-up care."

Rudd's associates in the study were M. Gail Price, Lewis E. Graham, Barbara A. Beilstein, Sylvia J. H. Tarbell, Peter Bacchetti and Dr. Stephen P. Fortmann.

NEW STUDENT DESIGN FOR BODY-POWERED ARM WINS FIRST PLACE

STANFORD—

An artificial arm powered by the body's own muscles has won three Stanford students a top place in an international engineering competition.

The mechanical limb, powered by a tricep muscle instead of an opposing shoulder, also promises to give below-elbow amputees a better alternative in body-powered prosthetics.

The arm's development began with a challenge posed by Maurice LeBlanc, research director of Children's Hospital at Stanford's Rehabilitation Engineering Center.

LeBlanc explained that the awkwardness of standard shoulder harness models deters most amputees from wearing any prosthesis. "Little research has been done in this area since World War II," he said.

This challenge piqued the interest of mechanical engineering students Scott Delp, Georgene Nielsen, and Robert Wood. With a grant from Children's Hospital at Stanford's Raffin fund, they designed, built, and tested the artificial limb they now call the "tricep power capture prosthesis."

Its simple, unconventional design eliminates the need for a shoulder harness and cables that can catch on clothing, Delp said. Contraction of the upper arm's tricep muscle simultaneously extends the forearm and opens the hand. A "nudge button" on the inner elbow allows the opening and closing of the hand or hook to be coupled or uncoupled with the extension of the forearm, Delp explained.

The main attractive feature of the prosthesis is that it is entirely contained on the amputated limb, Delp said.

As part of the project, Doug Franz, a below-elbow amputee and engineer with Hewlett-Packard, tested the new prosthesis. Although the initial prototype needs additional modification, Franz said, "it holds great promise as an alternative" to the shoulder harness.

The Rehabilitation Engineering Society of North America (RESNA) selected the tricep power capture prosthesis as one of five top place winners in their student competition.

The Stanford student design team will present their project at the ninth annual RESNA conference June 23-27 in Minneapolis, Minn. They hope to enlist others in the field to continue developing their idea into a practical device for below-elbow amputees.

NEW BOOK HIGHLIGHTS CONFLICTS IN INTENSIVE CARE NURSERIES

STANFORD—

When doctors make medical decisions, they are never completely sure they are right. They can only act in light of their knowledge, experience and intuition. But in all medical practice, it is assumed that if they ignore statistical probability without sufficient cause, they are acting against their patient's best interests.

Nowhere do these issues come into conflict more dramatically than in the intensive care nursery where modern technology tries to prolong life that has not yet begun, and often forces some to live when they are trying to die, according to a new book, *A Time to Be Born, A Time to Die* by Rasa Gustaitis and Ernle W.D. Young (Addison-Wesley, 272 pp. $18.95).

Gustaitis is a journalist and Young is a senior lecturer in medical ethics in the Stanford University School of Medicine and chaplain at Stanford University Hospital.

The well-publicized recent infant heart transplants, the case of Baby Jane Doe, who was brain-damaged but kept alive on orders of a court, and Baby Fae, who was given a a baboon's heart but died anyway, punctuate this complicated issue.

In one report a premature, 750-gram baby named Matthew was kept alive by heroic measures for nine months. The infant, his doctors determined, was a borderline case worth an attempt to save. It had been done before with babies smaller than Matthew who had been saved and went home perfectly normal and healthy.

In the hospital, Matthew contracted all the familiar intensive care nursery ailments—respiratory distress, pneumonia, viral and bacterial infections. While some preemies in neighboring incubators would die after months of lingering, Matthew outlasted them becoming "a kind of tiny hero, someone who refuses to give up," according to the authors.

"Babies like Matthew," Gustaitis and Young write, "are very hard to care for because their progress is slow and they have so many problems."

Some of the problems are iatrogenic, that is, caused by the treatments themselves. The breathing machines required to keep Matthew alive had damaged his lungs so that they could no longer perform their essential function. Matthew vomited intermittently, and had hernias and gastrointestinal obstructions.

Eventually, Matthew died of a galaxy of complications and the authors ask, "Was the expenditure of more than $530,000 on his care or the mental anguish suffered by his parents justified?"

"Such questions are important to consider, but they are not for those in the nursery to resolve," Gustaitis and Young reply. "In the intensive care nursery, the choices exist within the parameters of the resources made available. Reflections on the broader picture seem abstract, whereas Matthew (and his parents) are real."

But the problems in these tragic situations extend beyond the hospital. What happens, for example, to infants who are "salvaged" in the intensive care nursery only to grow up as disabled and permanent dependents?

"There is a notable imbalance between the resources invested in the initial rescue and the follow-through, just as there is a growing imbalance between rescue and prevention of prematurity," say the authors. "Services for the disabled have been cut nationally, even as the need for them has risen.

"We cannot demand aggressive life-saving treatment for borderline babies without also demanding that these children receive the support they require to live as well as possible."

6-23-86

more

The authors do not blame only physicians for using high technology beyond the point likely to be helpful, but society in general, which seems to have adopted "an absolute and inflexible sanctity of life point of view."

The recent Baby Doe regulations promulgated by the Reagan administration but struck down by the U.S. Supreme Court would not help, the authors argue.

The rules which would have required that infants be treated aggressively, no matter how great their disabilities, Gustaitis and Young predict, would make the intensive care nursery "a torture chamber" and would deprive infants unequipped to live of their natural right to die."

In delineating the problems through a series of case histories, Gustaitis and Young emphasize that about $2 billion a year is being spent on newborn intensive care nurseries for some 200,000 babies, or 6 percent of those born in the United States. But in spite of a drop in infant mortality to about 10.9 deaths per thousand in the 1970s, the United States had slipped from seventh place in 1954 to seventeenth by 1982.

Neonatal intensive care units have contributed little to lowering the incidence of low birth weight, they point out. Low-birth weights are common in poor, predominantly black urban areas where almost 30 percent of all births are reported as premature.

"Though there are ethnic and racial variations in prematurity rates—Asians and American Indians have low rates, blacks have higher ones than Hispanics and whites—the clearest links are with low educational status, poverty, and lack of prenatal care," report Gustaitis and Young.

In other countries reductions in infant mortality were the result of maternal health and prevention programs, they write. Moreover, in Great Britain and Sweden, where medical services are free and paid for by the government, decisions on whether low-birth weight infants should be treated aggressively are made on medical grounds alone and infants born weighing less than 750 grams are not routinely treated aggressively.

Modern science has erased the sharp dividing lines that have separated a fetus from a baby or life from death, the authors note. Organs can be sustained now long after consciousness appears to have vanished.

"The definition of human life is up for review," Gustaitis and Young conclude.

"This does not mean that less attention should be given to the protection of the rights of the newborn. It means these rights must be considered in their special relationship to the rights of others and in the context in which they are to be exercised."

The authors don't think this will be easy as long as society fails to accept death as part of life and admires and rewards technological innovation. But they also see a ray of hope.

As consumers a growing number of citizens have begun to assume personal responsibility for the nature of their investments (including health care costs), according to Gustaitis and Young.

"Americans have discovered that (most of the time) they do not really want to think doctors are God."

DRUG THERAPY IMPROVES RELAPSE-FREE SURVIVAL TIME IN PATIENTS WITH A RARE CHILDHOOD BONE CANCER

STANFORD—

Anti-cancer drugs significantly improve disease-free survival rates in patients with osteosarcoma, a serious bone cancer once considered nearly incurable, concludes a new international study.

The study, published in the June 19 issue of *The New England Journal of Medicine*, contradicts previous reports suggesting that drugs are of no benefit to patients with this disease, said Dr. Michael Link, the study chairman.

"We have concluded that chemotherapy is of definite benefit in this kind of cancer," said Link, who is an associate professor in the department of pediatrics at Stanford University School of Medicine, and a hematologist/oncologist on staff at Children's Hospital at Stanford.

Osteosarcoma is a fairly rare tumor that strikes approximately 600 individuals each year in the U.S., mostly children and adolescents, Link explained.

In the majority of cases, a bone around the knee or shoulder becomes cancerous, and without treatment the disease is uniformly fatal, Link said. Primary treatment requires surgical removal of the affected portion of bone or amputation of the diseased limb, Link explained.

But in most cases, the cancer recurs because the tumor has spread to other parts of the body before the disease is diagnosed, he said.

The two-year study of 113 patients examined whether drug treatment, in addition to surgery, helps prevent relapse. One group of patients was treated only with surgery, while another group received chemotherapy beginning immediately following surgery.

Two years later, just 17 percent of the surgery-only patients had survived without a relapse in contrast to 66 percent of the surgery-plus-chemotherapy patients.

The study results should help end uncertainty about the value of drugs in osteosarcoma therapy, Link said. "We recommend that chemotherapy be given to all patients with this disease," he added.

However, Link noted that the drugs—cyclophosphamide, bleomycin, dactinomycin, high-dose methotrexate, doxorubicin, and cisplatin—all have serious side effects, requiring most patients to spend considerable time in the hospital during chemotherapy.

Lowered blood count, liver damage, nausea and vomiting were frequent problems associated with the chemotherapy, the researchers reported. Two deaths were reported among the 90 patients who received chemotherapy, one of which came about as a complication of the drugs; the other death appeared to be caused both by tumor recurrence and infection, Link said.

"Even though these drugs can be toxic, we feel the results prove that chemotherapy is worth giving," he said. In fact, Link noted that when surgery-only patients in the study relapsed, the researchers then instituted chemotherapy for them.

But because of the toxicity, "patients should be treated in centers that have a lot of experience with treating this disease and expertise in administering intensive chemotherapy," he added.

Link noted that there is a history of controversy over the usefulness of chemotherapy for osteosarcoma.

Prior to 1970, the prognosis for the cancer was dismal, he recalled. Relapse caused more than 80 percent of osteosarcoma patients to die within two years after diagnosis, despite amputation, he said.

Survival rates improved significantly in the 1970s when doctors began using chemotherapy, in addition to surgery, to eradicate tumor spread, Link said.

But chemotherapy was called into question in the mid-1970s when researchers at the Mayo Clinic reported that relapse-free survival rates in osteosarcoma patients had significantly improved, even without chemotherapy.

"The implication was that survival times increased, but that chemotherapy did not account for the improvement," Link said. "The Mayo Clinic investigators concluded that something else had changed the disease's prognosis—maybe the disease itself had changed or patients were being diagnosed earlier."

Because the drugs produced such severe complications, many doctors began to wonder whether their purported benefits outweighed the risks. Link and his colleagues initiated the current osteosarcoma study to try to settle the question once and for all.

"We now feel that the Mayo Clinic findings were wrong," Link added. "This is just as nasty a disease as it ever was, but if you give chemotherapy immediately after surgery, the number of patients who survive without recurrence is significantly higher."

Link said that the study will continue for several additional years to determine whether chemotherapy improves overall survival, not just relapse-free survival time.

And he added that "although there has been a dramatic improvement in overall outcome for children with osteosarcoma during the past 15 to 20 years, refinements in therapy are needed" to improve limb-sparing surgical procedures, and to reduce the side effects of drug therapy.

In addition to Stanford University Hospital and Children's Hospital at Stanford, other participating institutions include the Dana-Farber Cancer Institute and Children's Hospital, Boston; the Pediatric Oncology and Surgery Branch, National Cancer Institute; St. Jude Children's Research Hospital in Memphis; Children's Hospital of Philadelphia; Great Ormond Street Hospital, Royal Marsden Hsopital and St. Bartholomew's Hospital in London; Washington University Medical Center in St. Louis, and multiple pediatric cancer centers of the Pediatric Oncology Group.

The study was supported by grants from the National Cancer Institute.

PALO ALTO—

MONTANA MAN GETS SPECIAL "FATHER'S DAY" GIFT FROM SON — A NEW SHOULDER AND ARM

Montana's best — and probably only — one-armed mandolin player, Clarence "Dude" Parker, recently received a special gift.

His 23-year-old son Doug Parker, a first-year Stanford medical student, custom-tailored a new shoulder joint and arm for his dad.

The new prosthesis, one outcome of a Children's Hospital at Stanford research project conducted by Doug, should help compensate for the real arm and shoulder Dude lost in a hay baler nearly 30 years ago.

The new shoulder — made of plastic surrounded by a soft skinlike foam — is the most "innovative" part of the prosthesis, according to Doug. "I imagine there is not another socket quite like it anywhere," he said.

According to Maurice LeBlanc, research director of Children's Hospital at Stanford's Rehabilitation Engineering Center, Doug's research project is helping to advance the state of the art in body-powered prosthetics. "There has been no substantial progress in this area since World War II," LeBlanc said.

Dude's new prosthesis — weighing about three pounds — replaces a "1957 vintage," ugly, cumbersome, six-pound, hard plastic prosthesis that no longer fits Dude properly and causes some pain, Doug said.

The new one has a locking elbow and a spring to open and close the hand. "It sure feels good," Dude said in a telephone interview from his home in Bridger, Mont., the town of 800 where he was born and raised.

Dude, now 68, was 39 at the time of the accident. According to Doug, Dude lost "everything right up to the shoulder blade." Therapists advised Dude to sell his cattle ranch and retire.

"Yup," Dude affirmed, "They told me I couldn't (maintain the ranch), but I decided I could."

And, with sheer determination, Dude did everything necessary — such as shoveling and building fences — with just one arm.

His left arm grew "incredibly strong." Dude went on to start and run a youth saddle club, Doug said. And then — about 10 years ago — he took up the mandolin.

"I use the fake arm as my pickin' arm," Dude said, admitting that it took awhile to coordinate. Dude now plays in country bars and is frequently recognized by strangers, Doug said.

The new prosthesis should make playing "easier on my shoulder," Dude added; the weight of the old "gets kind of tiresome."

6-12-86

more

Dude was fitted with the old prosthesis in 1957 shortly after the accident, but the muscles around the joint area later wasted away, leaving an extremely thin layer of skin over blunt bones, Doug explained.

A conventional prothesis is unsuitable for Dude because this area is so sensitive; "nothing can touch there," Doug said.

But when touched gently, nerve endings at these sites give Dude the sensation of feeling his hand. "Dad will say 'You are touching the palm of my hand' or 'There is the back of my hand,' " Doug said. This is a common phenomenon for amputees called "phantom limb," Doug explained.

Being able to relate such classroom information to his father's experience excited Doug and prompted him to seek out a research project. His adviser, Dr. Robert Chase, a renowned Stanford hand surgeon, referred him to LeBlanc.

With the help of LeBlanc and other staff members, and funded by a grant from the Stanford Medical School Scholars program, Doug began a project to enhance body-powered prosthetics.

The prosthesis that Doug built for his father incorporates many of his newly formed ideas about comfort and cosmetics. "It was fun using my new anatomy knowledge to give him back his pectoral muscle and his deltoid, trapezius, and rhomboids," Doug said.

And, likening the experience to sculpting, Doug said building the prosthesis brought back memories of the two years he spent in art school prior to enrolling in medical school.

Doug's overall project "is far from over," he said. His other ideas include a hydraulic-powered, cosmetic, hooklike "hand" and sensory devices that take advantage of the phantom limb phenomenon.

As a child "I often fantasized about building bionic arms or transplanting arms," Doug said. "The 'Six Million Dollar Man' was an important TV show for me when I was young," he noted.

Doug thinks his experience with his father will help him assist other people with a variety of disabilities. "It never occurred to me that dad would be considered handicapped," Doug said. His only memories of his father are with one arm. "If he had two arms he would look really strange," he added.

Doug said that instead of feeling pity, which disabled people don't want, "I can say 'You are a person and so am I; we have all got our problems. Let's see what we can do about yours.' "

STANFORD MEDICAL STUDENT RECEIVES GRANT TO DEVELOP COURSE ON SEXUALLY TRANSMITTED DISEASES

STANFORD—

Sylvia Cerel, a second year Stanford medical student, is one of 34 medical students nationwide chosen this year as a SmithKline Beckman Corporation Medical Perspective Fellow by the National Fund for Medical Education (NFME).

Cerel plans to use her $3,300 grant to develop a course on the biosocial aspects of sexually transmitted diseases (STDs) for Stanford's undergraduate program in human biology, and to create a curriculum for others to use.

The course, Human Biology 128, will be given winter quarter of the academic year 1986-87. Dr. Gary Schoolnik, assistant professor of medicine and medical microbiology, is the faculty sponsor.

Cerel, who is developing the course's content and readings, is inviting a distinguished group of guest lecturers including national experts on STD research and policy.

"This is not going to be just another course on sexually transmitted diseases," she explained. "We'll explore the behavioral and legal implications of these diseases, as well as their scientific, medical and epidemiological aspects.

"Until recently, the term 'venereal disease' was used to describe a limited number of conditions, including gonorrhea and syphilis," Cerel added. "Now the STDs number in the 20s, and include chlamydia, herpes and AIDS. We hope that studying the historical, legal and psychological implications of these diseases will provide students with a broader perspective on the current political and social problem of STDs."

Among the guest speakers will be Dr. Ward Cates, from the Centers for Disease Control, who will discuss STDs from a national perspective; Dr. King Holmes from the University of Washington, who will talk about STD research methods and problems; and Dr. Constance Wofsy from the University of California, San Francisco and Margo St. James, founder of Coyote, who will discuss STDs and prostitution.

Other guest speakers will discuss such topics as AIDS and the law, syphilis in western history, STDs and the media, and more.

The guest lectures will be announced in advance and will be open to the public, Cerel said, although course enrollment for credit will be limited to 30 students.

Cerel, an Atlanta native, established an interest in STDs while she was an undergraduate at Emory University and worked at a family planning clinic in Atlanta. She has carried out research on pelvic inflammatory disease at San Francisco General Hospital and collaborated with investigators at the Centers for Disease Control in producing a book on contraceptive technology in which she wrote a chapter on STDs.

NFME administers the Medical Perspectives Fellowship Program for the SmithKline Beckman Corporation, which has contributed over $1.1 million to fellow sponsorship since 1978.

The NFME was chartered by Congress in 1954 to mobilize voluntary support for medical education. Its primary mission is to promote the best possible health care for the American people through improvement in medical education.

FOUR STANFORD MEDICAL STUDENTS RECEIVE AMERICAN HEART ASSOCIATION FELLOWSHIPS

STANFORD—

Four medical students have been selected for 1986-87 American Heart Association (AHA) research fellowships at Stanford University School of Medicine.

The AHA fellowships enable the students to take one year out from the medical curriculum to pursue full-time research in a field related to cardiovascular disease, said Dr. Robert Kates, associate professor of medicine (cardiology).

The program was conceived by the AHA while Stanford cardiology division chief Dr. Donald Harrison was president of that association, Kates said. "The idea was to expose students to the research environment," he added.

"It's a very nice opportunity because it's a full year of research," noted Dr. John Steward, associate dean for student affairs.

The newest round of awardees will receive a stipend of $8,000 for 12 months beginning July, 1986, and $1,500 to cover travel expenses and health insurance. They also receive tuition credit and can arrange part-time research assistantships with faculty sponsors.

This year's recipients are:

- Deborah Clark, who will study regulation of adenosine receptors in the heart under the supervision of Dr. Brian Hoffman, assistant professor of medicine;
- Donnie Evans, who will study how human cardiac muscle cells adapt to disease or stress, in the lab of Dr. Frank Stockdale, professor of medicine;
- Berit Madsen, who is investigating hormonal control of circulation and body fluid homeostasis under the direction of Drs. Andrew Perlman, assistant professor of medicine, and Bryan Myers, associate professor of medicine;
- Gina Louie, who will investigate the effects on the heart of the anesthetic halothane, in the lab of Dr. Mervyn Maze, assistant professor of anesthesia.

Previous awardees in the fellowship program, which began in 1984, are Stuart Schlisserman and Eric Fain (1984-85), and Ali Karriem and Robert Hagberg (1985-86).

FOUR SCHOLARS AT STANFORD MEDICAL SCHOOL GIVEN LEUKEMIA SOCIETY AWARDS

STANFORD—

Four postdoctoral scholars at Stanford Medical School have been awarded three-year fellowship grants from the Leukemia Society of America.

Dr. Shelly Heimfeld and Dr. Leslie Berg were among 48 investigators nationwide awarded $70,500 Fellowship grants; Dr. Adam Geballe and Dr. Mark Danielson were among the 46 scientists who have received $87,000 Special Fellowships from the Society.

Heimfeld is studying with Dr. Irving Weissman in the pathology department the process by which blood cells differentiate, and how leukemia may result when this process goes awry.

Berg is working with Dr. Mark Davis in the medical microbiology department, where she is concentrating on how the body's immune system fights cancers such as leukemia.

Geballe, based in the lab of Dr. Edward Mocarski in medical microbiology, is investigating the viral basis of leukemia and related diseases.

Danielson is conducting his research on the molecular basis of malignant diseases in the laboratory of Dr. Gordon Ringold in the pharmacology department.

Overall, in the United States and abroad, the Leukemia Society currently supports 246 researchers with grants totaling approximately $6.2 million. All of the grants are committed to accelerating efforts to close in on the causes and eventual cures for leukemia and related diseases, according to the Society.

HEART ASSIST SYSTEM SAVES PATIENT'S LIFE

STANFORD—

A 47-year-old man was reported recovering at Stanford Medical Center Thursday (June 12) after an implantable mechanical heart assist system kept him alive long enough to receive a human heart transplant, doctors said.

Dr. Philip E. Oyer, professor of cardiovascular surgery, said, "This use of the system may address the needs of a large patient population which previously had little hope of survival."

The patient was identified as the Rev. Dr. William Rainford, a chiropractor and Episcopal priest from Santa Cruz. Oyer said his heart had stopped beating six times within several hours before doctors decided to implant the left ventricular assist device (LVAD), said Oyer.

It was the third implantation into a Stanford patient of the electrically-powered cardiac assist pump, developed by the Novacor Medical Corp. of Oakland for ultimate use as a totally implantable, self-contained cardiac support system, leaving the natural heart intact.

The current patient was brought to Stanford after he was already in shock, said Dr. Peer M. Portner, president of Novacor and a consulting associate professor of cardiovascular surgery at Stanford.

On Sunday, the patient's own heart and the device were replaced with a donor human heart during a second operation, Oyer said.

"There is no doubt that a dramatic intervention was necessary to keep the patient alive, said Oyer. "Without the use of the heart assist device, the man would not be alive now."

The patient, had been transported in cardiogenic shock (a critical drop in blood pressure) by Stanford's Life Flight emergency helicopter from Santa Cruz on Wednesday, after physicians determined that an implantable cardiac assist system offered his only chance for survival.

Rainford was reported in stable condition Thursday and was expected to remain in intensive care for at least a week following the two major operations, the surgeon said.

The patient suffered his first heart attack last year and was hospitalized after a second myocardial infarction occurred about two weeks ago, doctors said.

The LVAD is an electrically powered, electronically controlled pump that synchronizes with the natural heart's beat. It does not replace the heart, but rather, assists the weakened heart muscle by taking over the function of the main pumping chamber, the left ventricle.

The Food and Drug Administration in July 1984 authorized the trial use of the system in 20 patients at Stanford, and subsequently, in additional patients at other hospitals outside California.

The first patient, Robert St. Laurent, then 51, received the device in September 1984 and a human heart transplant eight days later. He is reported doing well at his home in Florida. The second transplant patient received the device in April 1985 but died 16 days later of pneumonia, Oyer said. Both patients suffered from terminal coronary artery disease.

Portner said the "bridge-to-transplant" model of the heart assist system is implanted in the body but powered by an external power unit.

Eventually, the large power console of the system undergoing tests at Stanford is expected to be replaced by an implanted controller and a compact battery pack, worn as a belt, which would transmit power to the system through the skin.

"This will enable severely incapacitated patients the opportunity to return to a relatively normal life," said Portner. In contrast to the artifical heart, the heart's natural regulatory function remains intact, allowing normal physiologic response to exercise and emotion, Portner explained.

Testing in animals of the battery-powered LVAD is expected within a month at Stanford, Portner said. He said the first human trials of the totally-portable battery unit are expected in about a year.

In addition to transplant candidates and persons suffering imminent death from circulatory collapse, the system could help patients who cannot be weaned from a heart-lung machine following otherwise successful open-heart surgery.

Portner, who holds a Ph.D. in experimental nuclear physics, has been involved in biomedical research for the past 16 years. Partial funding for development of the LVAD has come from the National Institutes of Health.

PREGNANT WOMEN WHO GET CHICKENPOX MAY BE AT RISK

STANFORD—

Chickenpox can be dangerous to pregnant women who have never had this infection, according to a report in the June 12 issue of *The New England Journal of Medicine* describing a Stanford Medical School study.

The chickenpox virus, called varicella-zoster, is passed from mother to fetus in approximately one in four of such cases but does not often damage the fetus, the study found.

The study also found that pregnant women who get shingles—caused by the same virus—do not appear to be at risk for serious complications and do not pass the infection to their unborn children.

The study was conducted by Dr. Sharon Paryani, a former postdoctoral fellow in pediatric infectious diseases at Stanford University School of Medicine who is now at University Hospital in Jacksonville, Florida, and Dr. Ann Arvin, associate professor of pediatrics at Stanford.

Both chickenpox and shingles are caused by the varicella-zoster virus; chickenpox, a contagious illness most commonly characterized by fever and skin pustules, occurs on initial infection, while the painful condition of shingles occurs when the dormant virus is reactivated in the body.

The study was carried out because specific information concerning risks of varicella-zoster virus infection during pregnancy has been limited, Arvin explained.

"This is because most adult women have had chickenpox, whether or not they have a history of infection," she said.

Chickenpox during pregnancy has been associated with a congenital syndrome in the newborn involving skin lesions, eye inflammations, limb atrophy, mental retardation and other birth defects.

But only a few infants with the congenital varicella syndrome have been described in the medical literature, Paryani and Arvin noted.

The researchers studied 43 pregnant women who contracted chickenpox during pregnancy and 14 pregnant women who became ill with shingles.

Nine of the 43 pregnancies complicated by chickenpox resulted in serious medical problems for the mother, including one woman's death (the six-month old fetus did not survive), four severe cases of pneumonia, and four cases of premature labor, two of which resulted in premature births.

6-11-86

more

Twelve percent of the infants who were examined after birth and then followed for a year had symptoms caused by infection with the varicella-zoster virus while in the mother's uterus, and 12 percent had immunologic evidence of infection but did not have symptoms, the researchers reported.

In contrast, there was no evidence that the virus was passed to the fetus among the 14 shingles-afflicted expectant women, although one woman had minor complications.

"These observations show that varicella (chickenpox) during pregnancy was associated with maternal morbidity and evidence of fetal infection, but that herpes zoster (shingles) was not," the researchers wrote.

The new study found that only one infant was born with the classical varicella syndrome. This infant's mother was one of 11 who became ill with chickenpox during the first trimester of pregnancy. None of the mothers who got the disease in the second or third trimesters gave birth to children with the classical congenital varicella syndrome, the researchers reported.

These results, combined with others from previous studies, "indicate that varicella in the second and third trimesters is rarely associated with birth defects," the researchers wrote.

"Although complications did not occur in the majority of women, the maternal risk justifies the administration of varicella-zoster immune globulin to pregnant women who have no (immunity) to varicella and who have had a close exposure to the varicella-zoster virus," the researchers concluded.

However, "the effectiveness of (the) immune globulin in preventing fetal complications is unknown," they said.

The varicella vaccine which is being developed should also be beneficial for women of childbearing age who have never had chickenpox, Arvin added.

THE MOST EXCLUSIVE CLUB IN THE WORLD?

STANFORD—

At 7 p.m. on the third Thursday of every month, a group of ordinary looking men and women file into an ordinary building in Palo Alto for a meeting of one of the most exclusive clubs in the world.

There is only one requirement for joining the club, but it is one that rules out all but a tiny fraction of the world's population: Members must be heart transplant recipients.

Transplant recipients Linda Lamb and John La Bissoniere formed the club, called Cardiac Transplant Support, in January of 1985. "We thought there was a need for something like this—to communicate with someone who has had the same experience you have," Lamb said.

Meetings are held in a room provided by California Federal, a savings institution on El Camino Real in Palo Alto. The meetings are basically to provide communication and support, with recipients asking questions of each other and sharing their experiences.

About one meeting in three features a guest speaker, frequently one of the post-care transplant nurses at Stanford University Medical Center, where Lamb and La Bissoniere received their new hearts—in fact, where all club members so far had their transplant operations.

"The nurses give us the medical advice that is available and review our conditions and talk about symptoms and things like that," Lamb said. "They don't describe the surgery; they talk more about medication effects and other effects."

Although membership in the cardiac club is restricted to those who have had transplants, meetings are often attended by potential members: people waiting for transplants.

"We're not very strict (about attendance)," La Bissoniere said. "And a lot of pre-transplants are very interested in attending."

Anyone can attend one of the club's two scheduled yearly social events, a Christmas party and a wine tasting. The wine tasting will be held from 5 to 8 p.m. June 19 at Rickeys Hyatt House Hotel in Palo Alto, and the invitation list includes doctors, nurses, transplant candidates and recipients and their families and friends.

The Christmas party and wine tasting are fund-raising events. Prizes have been donated by restaurants and other businesses and will be raffled off.

Eventually, Lamb said, the club would like to raise enough money to provide financial support to some transplant candidate or recipient who needs assistance.

Right now, though, Lamb and La Bissoniere are concentrating on building up membership. That isn't easy, considering the limited number of available candidates.

Even when a new member signs up, he or she is likely to be gone in a few months—as soon as Stanford doctors give the OK to return home. Since only a handful of transplant recipients lived in the area originally, the club depends heavily on those who came to Stanford for transplants and liked the area enough to remain.

That was the case with both Lamb and La Bissoniere. Lamb, 25, came from Ohio for a transplant done in October of 1983. She and her husband, Tom, decided to remain and now live in San Mateo in an apartment building he manages. La Bissoniere, 34, came from Southern California for a transplant in December of 1979. He now lives in Cupertino and works full time at the American Heart Association in San Jose.

Lamb also worked for a time at the heart association, and it was there that she and La Bissoniere met, became friends and decided to form Cardiac Transplant Support.

NEW MEDICAL LINEAR ACCELERATOR INSTALLED AT STANFORD

STANFORD—

A new, state-of-the-art medical linear accelerator—the Clinac 1800—to enhance Stanford University Hospital's radiation therapy capabilities, will begin operations this summer.

With beams of electrons and X-rays, the new Clinac 1800, made by Varian Associates of Palo Alto, will be used to battle a variety of cancers, according to Dr. Malcolm Bagshaw, professor and chairman of the department of radiology. It will also be used experimentally to treat autoimmune diseases and prepare patients for organ transplants, he said.

The Clinac 1800 features two new low electron beam energies and enhanced controls for penetration and accuracy; several standard electron and X-ray beam energies are also available, Bagshaw said.

The room that houses the accelerator is specially designed to contain radiation. It has round walls and a two-foot-thick, steel-and-concrete ceiling that weighs 160,000 pounds. It can only be entered through a curving corridor that scientists call a maze.

Both the room and accelerator are part of a large, $2.1 million project to boost the services of radiation therapy.

The new medical linear accelerator is Stanford's fourth. The accelerators have been used successfully to treat several types of cancers including cancer of the prostate, breast cancer, Hodgkin's disease, and other cancers of the lymphatic system.

The low electron energies and total body radiation capabilities make the Clinac 1800 also well-suited for treating skin malignancies, particularly mycosis fungoides, "a rare and terrible" skin cancer, Bagshaw said. Stanford is a major referral center for mycosis fungoides; more than 400 people with this cancer have been treated here, he said.

Radiation therapy, surgery, and drug therapy are the standard cancer treatments. However, the use of medical linear accelerators has been expanded to include patients who require immune suppression.

Radiation therapy at Stanford is also being used in conjuction with hyperthermia, heat therapy. Applying heat to cancer cells makes them more susceptible to radiation, Bagshaw said.

Accelerators are also "essential for total body bone marrow transplants," Bagshaw said. Radiation is used to "wipe out" a person's own bone marrow so that donated bone marrow can be transplanted, he said.

Medical linear accelerators hurl electrons and X-rays at cells targeted for destruction, such as cancer or bone marrow cells. The new accelerator gives electrons selected energies by speeding them along a six-foot path, "riding a microwave beam," Bagshaw said. Then, the electrons are either aimed directly at their target or first converted into X-rays.

The accuracy of the Clinac 1800 is plus or minus one millimeter, Bagshaw said.

Rotating delivery systems in medical linear accelerators maximize radiation to target (cancer) cells, and minimize radiation to non-target (healthy) cells by delivering it from different angles.

Another machine, called a simulator, is used to plan treatments with the accelerator. This medical linear accelerator look-alike, equipped with X-ray diagnostic equipment, mimics motions and positions of accelerators.

A new simulator—a Zimatron—will accompany the new Clinac 1800, Bagshaw said. Such instruments, in conjunction with precisely aligned laser lights, cut the time required to position patients within the accelerator for treatment.

The time saved is tremendous. In cancer treatments, radiation is usually given one or two times each day, five days each week, for approximately six weeks, "and sometimes up to four months," Bagshaw said.

The prototypes for both simulators and medical linear accelerators were initially developed at Stanford, he said. The first medical linear accelerator in the western hemisphere was developed by the late Dr. Henry S. Kaplan, Stanford's first chairman of the department of radiology and Dr. Edward Ginzton, former Stanford professor and chairman of the board of Varian Associates, he said.

It was built at the Stanford Microwave laboratory and installed in the old Stanford Hospital in San Francisco in 1955. Its descendents have become the "standard workhorses of radiation therapy worldwide," Bagshaw said. It is now housed in the Smithsonian Institution.

STANFORD ALCOHOL, DRUG TREATMENT CENTER ACCEPTS FIRST PATIENTS

STANFORD—

The new Stanford Alcohol and Drug Treatment Center has opened and is accepting its first patients in a hospital setting, co-directors Robert Matano and William Hazle announced Thursday, June 5.

The 13-bed inpatient center is situated in the Hoover Pavilion. Structured and long-term outpatient care will continue to be offered at the Stanford Alcohol Clinic.

Matano and Hazle noted, however, that the nine-year-old clinic has moved into new offices in the new Medical School Office Building, across the Medical Center parking lot from the old headquarters in the Psychiatry Building.

Combining the outpatient care of the alcohol clinic with the inpatient treatment of the new center gives Stanford the ability to treat "pretty much every problem that is alcohol and drug related," Matano said.

Matano is director of services and Hazle, an M.D., is medical director of the new center. They have emphasized that the length of inpatient hospitalization at the center will be determined by individual patient needs, unlike programs at some treatment centers that require 28- or 30-day stays, and the focus will be on the long-term process of recovery.

Structured outpatient services and long-term therapy are combined with the shorter hospitalization. The treatment model will be effective in providing individualized and comprehensive therapy, Matano and Hazle said.

For more information, telephone (415) 723-6682.

STANFORD'S HEART-LUNG TRANSPLANT PROGRAM LEADS TO NEW BASIC INFORMATION ABOUT ORGAN FUNCTION

STANFORD—

Transplantation does not adversely affect the long term function of lungs that have been separated from their nerve supply as well as from the respiratory and circulatory systems, Stanford University Medical Center researchers have established.

"Despite the fact that they have been denervated, the lungs seem to be a self-functioning unit," said Dr. James Theodore, associate professor of respiratory medicine.

Not only are the lungs unaffected by transplantation, he added, but there seem to be few adverse effects on them during exercise or on ventilation, the actual process of inhaling and exhaling air.

This information is just one spinoff of Stanford's heart-lung transplant program. It contradicts some important basic concepts of human physiology, Theodore said, which state that the lungs function as an integral component of the respiratory and circulatory systems, and that the integration of function between them is controlled primarily by the central nervous system.

"We have a unique situation here because Stanford happens to have an active transplant program," said Theodore, a pulmonary specialist. Stanford cardiovascular surgeons have performed 34 combined heart-lung transplants since 1981. Of these patients, 20 have been studied for as long as three years after the transplant.

These studies have given Theodore and a group of physicians and technicians in Stanford hospital's pulmonary physiology laboratory the opportunity to begin discerning normal from aberrant function of the lungs. In addition to rewriting some basic tenets regarding the basic physiology of the lungs, they are able to use their findings to modify and improve the care of heart-lung transplant patients.

The work is important, Theodore said, because "in order to pick up the subtle abnormalities that may come from disease, such as rejection, we have to define what the normal functions are."

6-5-86

more

The physicians have already been able to detect some potentially lethal problems, the most significant of which is a complication called obliterative bronchiolitis, he said. Nearly half of Stanford's transplant patients have developed this condition in which the patient's airways become obstructed. If not detected and treated, it can lead to permanent damage of the lungs and necessitate a second transplant, Theodore said. By learning how to detect it, however, the physicians can aggressively treat it in order to avoid its effects.

"We are basically starting from scratch in defining the function of the lungs and how transplantation affects them," Theodore said. Yet overall, the studies conclude, when there are no complications, "the transplanted heart and lungs perform sufficiently well to support the activities of normal life."

At the Third Annual International Symposium on Applied Circulatory and Respiratory Physiology in Anesthesia and Intensive Care in Rotterdam last fall, Theodore presented an overview of the work he and his colleagues have been doing.

"No one had established what the functional status of transplanted lungs would be over a long period of time," Theodore said. "The main thing we've learned is that transplantation, per se, does not adversely affect long term function of lungs despite the fact that they have lost their nerve supply, and they have been separated from the other systems." The transplant procedure does not seem to adversely affect patients during exercise or ventillation either, he added.

The physicians found that the lungs do not limit transplant patients' ability to exercise. Rather, their exercise capacity is determined to a large extent by limitations due to their illness prior to transplantation.

Breathing, blood flow and the exchange of oxygen and carbon dioxide also continue normally with transplanted lungs. What this means, Theodore said, is that these functions are regulated from within the lungs. "Even though the lungs are no longer hooked up to a bigger system they still work within it," he said. "They don't seem to be greatly influenced by external factors."

"You have to understand the entire system in order to understand each individual part," Theodore explained. "Once you define what is normal, you know how to treat problems that arise."

INSTABILITY AMONG WEAPONS PERSONNEL HEIGHTENS RISK OF NUCLEAR EXCHANGE

STANFORD—

Drug and alcohol abuse, fatigue, psychological instability, and job-related stress among personnel who handle nuclear weapons may heighten the danger of an accidental or inadvertent nuclear exchange, contends a Stanford University professor.

The danger is greatest during periods of extreme international tension when some of the usual safeguards against weapons firing may be temporarily loosened, warns Dr. Herbert Abrams in an article in the July/August issue of *The Sciences* magazine, a publication of the New York Academy of Sciences.

At such times, miscalculation, misperception or misunderstanding might lead to a catastrophic decision, said Abrams, professor of radiology at Stanford University School of Medicine and member-in-residence of the Stanford Center for International Security and Arms Control.

Instability among nuclear weapons workers plagues both the United States and the Soviet Union, Abrams said, despite military screening programs designed to select competent and reliable personnel.

Although no independent evaluations of these screening programs are available, indirect information suggests that they are, at best, imperfect, he added.

The U.S. military's Personnel Reliability Program (PRP), for example, screens candidates for nuclear weapons unit commanders, pilots, crews, and delivery personnel as well as security guards, supply and launch personnel, Abrams said.

But defense department figures indicate that among those who pass the screening, on average more than five thousand each year are decertified for a variety of causes including drug abuse (33 percent), alcohol abuse (nine percent), breaking the law (16 percent), and other psychological, behavioral or physical reasons (21 percent).

"The high rate of decertification is disturbing because it suggests the inherent weaknesses of the PRP as a screen for stability," Abrams wrote. "As a result, at any given time, thousands of potentially unstable individuals have day-to-day responsibility for handling nuclear weapons.

"As recently as last year, 1400 individuals were decertified from nuclear weapons handling because of drug and alcohol abuse," Abrams reported.

The problem of finding reliable personnel is compounded because "the military population in general suffers from high rates of drug and alcohol abuse and other psychiatric disturbances," Abrams explained.

A 1980 defense department survey showed that 36 percent of military personnel admitted to using illegal drugs, and a 1981 survey of personnel at U.S. military installations in Italy and Germany revealed that drugs were used on duty by 43 percent of army personnel, 17 percent of air force personnel, 35 percent of marines, and 49 percent of navy personnel.

Defense department officials also testified before Congress in 1982 that an estimated 28 percent of army personnel and 21 percent of naval personnel drank while on duty, with the highest prevalance of drinking reported among senior officers, Abrams said. Although drug abuse in the armed forces has decreased in recent years, he noted, it remains an urgent problem for nuclear forces.

Details remain secret about the probable Soviet counterpart to the U.S.'s Personnel Reliability Program, Abrams said. "Still, the Soviet military appears to be afflicted with many of the same staffing problems faced by the U.S. armed forces," including a small applicant pool for submarine patrols, which leads to lowering of selection standards, he added.

In the Soviet Union, alcohol rather than hard drugs, appears to be the greatest problem. According to Abrams' article, one U.S. army expert contends that alcohol abuse in the Soviet military is even more common than in the Soviet population at large where it is thought to be a problem of epidemic proportions, producing 100 times the number of acute alcohol-related deaths as the U.S..

Nuclear weapons work itself is likely to exacerbate drug- or alcohol-induced instability, Abrams suggested. "The isolation aboard nuclear submarines and in nuclear missile silos, unnatural work shifts and, in times of emergency, the extreme stress involved in being responsible for nuclear weapons all are likely to affect job performance," he pointed out.

A large body of psychological research has established the severe emotional consequences of prolonged isolation, including depression, irritability and hostility, Abrams said. In addition, rotating work shifts disrupt the body's biological clock, which controls the sleep-wake cycle, release of hormones, and other physiological processes. This can lead to emotional disturbance, impaired coordination, and job peformance problems, he said.

Despite these human instability factors, peacetime safeguards are likely to prevent the inadvertent firing of a nuclear missile or other weapon, Abrams said.

"The problem arises during crisis when measures to guard against inadvertent launches tend to undermine launch readiness," he argued.

Most United States nuclear weapons are fitted with permissive action links, electronic locks whose "keys" are supplied by the National Command Authority (the president and secretary of defense), Abrams explained.

In addition, "Before an intercontinental ballistic missile can be fired, a total of four officers at two sites...must decide individually to launch the weapon," he added.

But, during a crisis, "to ensure that their forces are able to respond rapidly to an attack, commanders on both sides may loosen safeguards—issuing advance authorizations, reducing the number of people necessary for a launch, or partially 'enabling' weapons so they could be fired quickly," he said.

Furthermore, "controls over firing of submarine-launched ballistic missiles are less stringent," Abrams said. "The navy maintains no permissive actions links on SLBMs, arguing that authorization codes transmitted from Washington could be disrupted...The captain and crew of a nuclear submarine are supposed to receive higher authorization before firing a missile, but if they should decide to act independently, there are no technical safeguards to prevent them from launching the weapon," he said.

This kind of situation may open the way "for unstable personnel to exert control over nuclear weapons," Abrams concluded.

STANFORD INTERFERON PIONEER PREDICTS FDA APPROVAL MAY SPEED USES OF OTHER GENETICALLY ENGINEERED DRUGS

STANFORD—

The Food and Drug Administration's (FDA) approval of a genetically engineered form of interferon for one type of cancer is an "exciting beginning" in bringing genetically engineered drugs into everyday medical practice, a Stanford doctor predicts.

"This approval should accelerate the introduction of other forms of interferon and other recombinant products into clinical practice," said Dr. Thomas Merigan, a pioneer in interferon research who was a member of the FDA committee recommending the drug's approval.

In 1978, Merigan and colleagues at Stanford University School of Medicine were the first researchers to report a positive clinical response when interferon was used to treat patients with B-cell lymphoma.

The FDA today (June 4) announced that it had approved the use of alpha-interferon, produced through recombinant DNA techniques, for treatment of a rare form of cancer called hairy cell leukemia.

Clinical tests conducted at several medical centers around the country, have shown that alpha-interferon is effective in reducing or eradicating hairy cell leukemia in 90 percent of patients, Merigan said.

Although hairy cell leukemia is estimated to affect fewer than 1,000 patients in the United States each year, it is closely related to other forms of cancer that affect the white blood cells known as B-lymphocytes, noted Merigan, Becker professor of medicine at Stanford University School of Medicine.

Now that the drug has been approved, it's likely that clinical trials of interferon will speed up for other diseases that affect many more individuals, he suggested.

For example, interferon may prove useful in treating other types of B-cell lymphomas, which altogether afflict as many as 30,000 people in this country each year, he said.

Another potential application of alpha-interferon being studied at Stanford is in preventing relapse of certain types of lymphomas that afflict 10,000 new patients each year, he added.

Interferon is one member of a class of natural body substances called lymphokines, hormones that help activate the immune system to combat infection and cancer.

"There are other genetically engineered lymphokines coming down the pike that show promise," Merigan noted.

One such lymphokine is interleukin-2, which in preliminary clinical tests appears to have activity against a wide variety of cancers, Merigan pointed out.

City desks: Telephone numbers of individuals interviewed for this story are: Dr. Edgar Engleman, Stanford Medical School Blood Center, Palo Alto, (415) 725-4463; Dr. Herbert Perkins, Irwin Memorial Blood Bank, San Francisco, (415) 567-6400; Dr. J. Lawrence Naiman, American Red Cross Blood Service, San Jose, (408) 292-6242; and Evelyn Bijak, Peninsula Memorial Blood Bank, Burlingame, (415) 697-4034 Ext. 40.

LOCAL LEADERS DEPLORE COMMERCIALIZATION OF BLOOD SUPPLY

STANFORD—

Putting one's own blood in the freezer for a "rainy day" when there is no expected need for its use is costly and wasteful, leaders from four San Francisco Bay area community blood banks said Monday (June 2).

The leaders' criticism was directed at commercial (for profit) enterprises that advertise in newspapers, encouraging autologous donations—units drawn from and used by the same person—as the safest kind of blood that can be frozen and stored up to three years for future use.

"They (the for profit enterprises) appear to be capitalizing on the fear of AIDS and what some people see as an investment opportunity on which they expect a return," said Dr. Herbert Perkins, medical director of Irwin Memorial Blood Bank in San Francisco.

That self-donated blood is the safest is not the issue, the leaders stressed. Community blood banks, including Stanford's, are also encouraging people who might need blood for surgery to donate for themselves in their blood bank as soon as they know that surgery is necessary. Liquid blood, which has a shelf life of six weeks, can then be used for anticipated needs.

"Autologous blood for transfusion eliminates all risks of infection, disease and incompatibility reactions," said Dr. Edgar Engleman, associate professor of pathology and director of the Stanford Medical School Blood Center in Palo Alto.

"But if surgery is not planned, the likelihood of that blood being used is remote," Engleman said.

Perkins noted that under Food and Drug Administration rules frozen blood can be stored for three years. "But the chance that a healthy person will need a blood transfusion within the next three years is so low as to be ridiculous to worry about," he said.

The main advantage of self-donated blood is prevention of non A, non B hepatitis, a potentially serious viral disease for which there is no test, said Dr. J. Lawrence Naiman, medical director of the Central California Region of the American Red Cross Blood Service in San Jose.

AIDS is now a lesser concern, he added, because the risk of AIDS from blood tranfusions has been virtually eliminated by the introduction of routine donor testing for antibodies to the AIDS virus.

6-2-86

more

"Most healthy individuals never require blood transfusions in their lifetime," Naiman said. "The chances that an individual might need this blood are e tremely small. Therefore, it sits in the freezer depriving members of the community of a very valuable resource."

Naiman added that frozen blood cannot always be thawed in time for emergency use, and it provides only red blood cells, not plasma or platelets that might be needed to stop bleeding.

Evelyn Bijak, administrator of the Peninsula Memorial Blood Bank in Burlingame, said, "If your blood is frozen and you need it, you first have to be conscious to tell people where it's stored, and hope that you're not in Eureka where you had the car accident."

Bijak said self-donated blood is the safest for the patient in cases of planned surgery. "But at Peninsula we also feel that the blood available through a volunteer pool is extremely important and safer than it has ever been," she added.

What do the experts think about the commercialization of blood banking?

"It's not good for the community," said Naiman. "It's potentially capitalizing on the fear of AIDS and possibly will have a negative impact on the community blood supply. In essence those enterprises encourage people to hoard blood for themselves on the extremely remote chance that it will ever be used."

"It's an elitist kind of thing, a choice for those who can afford it," said Perkins. "An autologous donor dealing with these outfits will have to come up with the cash up front. He can't charge it to his insurance and in addition he pays for blood storage. As a form of insurance it's a bad choice to invest time, money or anything else."

Community blood banks, he explained, charge for blood when it's tranfused. There's no charge for storage.

Engleman said commercial enterprises charge between 30 and 50 percent more for liquid autologous blood than Stanford or other community blood banks.

Bijak said that people who donate blood are giving, caring types of individuals who want to help others. "I am sure they will continue to donate blood to the volunteer pool rather than store it for their personal use," she added.

STANFORD FILES PATENT INFRINGEMENT SUIT AGAINST FLORIDA COMPANY

STANFORD—

A patent infringement suit has been filed by Stanford University against a Florida-based biotechnology firm, University officials disclosed today (June 2).

The suit, filed in United States District Court in Florida, alleges that Coulter Electronics of Hialeah, Florida, has been selling patented fluorescent pigment compounds, called phycobiliprotein conjugates, without a license.

Stanford seeks an injunction against Coulter to stop sales of the contested products and also seeks damages.

The patent infringement suit is the first Stanford has initiated, said Katharine Ku, acting director of the University's Office of Technology Licensing.

The suit is based on a patent issued to Stanford in May, 1985, for the fluorescent pigments when they are attached, or conjugated, to other biological materials such as antibodies or cells. The brilliant blue and red pigments, made by marine algae, act like tiny fluorescent beacons, enabling researchers to detect substances at minute concentrations.

The pigments fluoresce with 10 to 20 times the intensity of most other fluorescent "tags," making them the first real viable alternative to high-sensitivity radioactive labels, Ku explained.

They have wide potential in research and clinical laboratories, where they can be used in flow cytometry, a method of counting and sorting cells, Ku said. They can be used clinically to screen donated blood for abnormalities, and to monitor blood levels of drugs in patients, she added.

Two companies—Becton Dickinson of New Jersey and Applied Biosystems of Foster City, CA—have been exclusively licensed by the University to use the phycobiliprotein conjugate technology. To date, Applied Biosystems has sublicensed the technology to 12 other companies, Ku said.

The phycobiliproteins were developed by Dr. Lubert Stryer, professor of cell biology at Stanford University School of Medicine, Dr. Vernon Oi, formerly a Stanford postdoctoral scholar and now at Becton Dickinson, and Dr. Alexander Glazer, professor of microbiology at the University of California, Berkeley.

The patent was sought by both Stanford and the University of California. The two institutions share royalties accrued through the licensing program, Ku said.

STANFORD MEDICAL ALUMNI HOLD SPRING SYMPOSIUM

STANFORD—

The Stanford Medical Alumni Association will hold its annual spring symposium, "The Application of Basic Research to Clinical Care," on June 7, 1986 in Sherman Fairchild Auditorium.

The symposium will feature talks by four medical school faculty: Dr. Irving Weissman, professor of pathology; Dr. Edgar Engleman, associate professor of pathology and medicine and medical director of Stanford's blood center; Dr. Stanley Falkow, professor of medical microbiology and medicine; and Dr. Stuart Young, associate professor of radiology.

The keynote speaker will be Dr. Nancy Ascher, assistant professor of surgery and director of the liver transplant program at University of Minnesota. Her talk is entitled "Liver Transplantation Comes of Age: New Twists to an Old Story."

The day's activities include a cocktail party for alumni, associates, spouses and faculty hosted by medical school dean and vice president David Korn. Class reunions will be held for the classes of 1941, 1946, 1951, 1956, 1966, 1971 and 1976. The class of 1936 will hold its 50-year reunion, and the class of 1961 will hold its 25-year reunion.

For more information or for registration, call the alumni office at (415) 723-5064.

OPERATIONS RESTORE MAN'S VISION, USE OF LEGS

STANFORD—

Blind, wheelchair-bound Steven Raymond came to Stanford University Medical Center in May for an unusual series of operations—and walked out on his own, able to see where he was going.

The 70-year-old Raymond hadn't taken a step in four years and couldn't tell night from day when he entered the medical center. Thirty-two days later, he went home, his problems corrected.

"It was a miracle to me," he said. "I've told everyone, 'a miracle down there (at Stanford) isn't anything; they do it every day.' "

Raymond's multiple operations involved a hip replacement by Dr. Stuart Goodman, assistant professor of orthopedics, and cataract removal by Dr. Peter R. Egbert, associate professor of ophthalmology.

They were made possible by a bit of adroit scheduling by Heather Blyth-Foss, clerical supervisor in the eye and orthopedic clinics. She knew Raymond was coming to Stanford from a distance—his home is in Live Oak, 35 miles north of Sacramento—and she was able to accommodate his desire to have his operations completed in one hospital stay.

When the operations were over, Raymond was transformed from a man confined to a wheelchair and dependent on a seeing-eye dog to one able to walk about on his own, going where he chooses.

The joy he finds in such freedom was evident as Raymond, a robust man with a hearty laugh, walked through the Stanford corridors on a recent follow-up visit.

Before the operations, he said, "I couldn't take one step and couldn't tell daylight from darkness. I had about given up."

He had the hip replacement first, then his eyes were operated on one at a time. For some reason, he said, he wasn't aware of any change in his vision until the day after his first eye operation.

"I was having orange juice, sitting on my bed and I happened to look up," he said. "I saw what turned out to be a calendar and it had a card with the number 2 on it.

"Gradually, it dawned on me. I called the nurse and said, 'Do you see that? I think that's a calendar over there. It says today is the second.'

"She said, 'That's wrong; it's the third.'

"I said, 'I don't give a damn about that.' And then she said, 'You *did* see that, didn't you?' "

Raymond has lived for the last 20 years in Live Oak, but before that he lived and worked all over the world.

He was born in New Mexico and is a Comanche Indian. "I didn't speak English until after I was 5 years old," he said.

Once he started in school, however, he picked up English—and most other subjects—rapidly. He eventually attended Carlisle Indian Schools in Carlisle, Pa., and earned a degree in engineering.

He traveled a lot as an engineer, building schools and highways in many parts of the country, and he traveled a lot on his own. At one time or other, he has visited every continent on Earth, he said.

It was particularly difficult for a man with such an adventuresome spirit to be unable to get around on his own. "You know, I hated that wheelchair," he said. "For four long years, I counted every day."

Now Raymond is counting only the extra pounds he put on during four years of inactivity. He and his guide dog may both start an exercise routine, because the dog had little to do and "gained weight, just like I did" during the past four years.

PEOPLE WITH POSITIVE AIDS ANTIBODY TEST DO NOT ALWAYS TRANSMIT INFECTION TO SEXUAL PARTNERS

STANFORD—

People who test positive for antibody to the AIDS virus do not always transmit the infection to their sexual partners, according to a study conducted at Stanford University Medical Center.

The study included nine couples, in six of which one person had antibodies to the AIDS virus. In only two cases did researchers find that a person had passed the virus to a partner.

Indeed, two persons who actually had AIDS did not infect their partners.

"Even after long periods of sexual contact, . . . not all subjects in our study with antibody . . . transmitted the virus," reported Drs. Harold Burger, Barbara Weiser, William Robinson, and others in the July issue of the *American Journal of Medicine*.

Nevertheless, "We are advising all (people) at increased risk for AIDS to use condoms," said Weiser, who is now at the State University of New York at Stony Brook.

The Stanford study only followed a small group, she noted. "Of course," she said, "researchers need to extend (our results) to a larger population."

The other researchers on the study were Drs. Jeffrey Lifson and Edgar Engleman of Stanford, and Drs. Jean-Claude Chermann, Luc Montagnier, Francoise Barre, Christine Rouzioux, and Francoise Brun-Vezinet of the Institut Pasteur in Paris.

Most research on sexual transmission of AIDS has involved people with multiple partners, according to Weiser. But in the Stanford study, she said in a telephone interview, two thirds of the subjects had been monogamous for at least a year, some for several years. For some of these subjects, "one can conclude from whom they contracted the virus," she said.

In two cases, men with antibodies to the AIDS virus in their blood appear to have infected their wives, the researchers noted.

One man had AIDS, yet the wife has remained well despite a positive antibody test. The other man was healthy, but his wife developed AIDS.

The woman with the positive antibody test also had decreased numbers of immune cells, called T helpers, which are killed when infection with the AIDS virus takes place. Yet she has subsequently recovered a normal level of these cells, according to Robinson.

A bisexual man in the study, who had AIDS and was also a hepatitis carrier, seems to have given the hepatitis virus to his female partner. Yet she has no antibodies to the AIDS virus in the blood, and she is healthy.

Hepatitis and AIDS are transmitted by the same routes—blood and semen, Robinson said. Yet AIDS appears to be less infectious, Weiser explained, probably because body fluids contain fewer of the viruses that cause AIDS, as compared to hepatitis.

The researchers followed a total of nine couples, both homosexual and heterosexual, from the San Francisco Bay area. At least one member of each couple was at risk for AIDS—they were either homosexual, bisexual, had received blood products for hemophilia, or had prior sexual contact with an AIDS patient.

All partners in the study had regular sexual contact with each other for more than a year.

The scientists sought clues on how the AIDS virus might spread but could find "no clear pattern" of transmission, according to the report.

Weiser said that the researchers had advised couples in the study to use condoms to prevent transmission of virus, but, she added, this advice was given at the time of antibody testing, and came too late for those who tested positive.

Yet infection may not always lead to the disease itself, Weiser said. In the case of the woman infected by her husband but who remained well, the couple had started using condoms after the woman's positive test. However, Weiser pointed out that their sexual relations fairly soon ceased due to her husband's continuing illness and subsequent death.

The researchers noted in the report that some subjects may have had low levels of the AIDS virus in their blood or semen and thus may not have transmitted infection, despite a positive antibody test.

Future studies should therefore isolate the actual AIDS virus from the blood of subjects, to learn more about how the disease spreads, the researchers wrote.

Unfortunately, Weiser said, techniques to isolate the AIDS virus now are "difficult, expensive and potentially hazardous" to perform, and routine tests that detect the virus itself "may be years away."

ADVANCE FOR RELEASE FRIDAY, JULY 25, 1986

MOLECULAR "LOCK-AND-KEY" RECEPTOR SYSTEM COULD PROVIDE BASIS FOR NEW TREATMENT AGAINST RHEUMATOID ARTHRITIS

STANFORD—

A new finding by Stanford University School of Medicine researchers raises the possibility that more effective treatments could one day be developed to treat rheumatoid arthritis, a disease that afflicts as many as two million people in the United States.

The new information, published in the August 1 issue of *Science* magazine, points to the existence of a molecular "lock-and-key" system that controls the entry of white blood cells, or lymphocytes, into the joints of rheumatoid arthritis patients.

Lymphocytes are the white blood cells that serve as the foot soldiers of the immune system. Normally, they help fight invading bacteria and viruses. But in rheumatoid arthritis, they are thought to play a crucial role in the abnormal growth of joint lining tissue, called synovium, leading to the pain and crippling swelling associated with the disease.

The new finding suggests that it may be possible to find a drug or other agent that prevents the destructive lymphocytes from entering the besieged joints without affecting the cells' ability to migrate into other tissues where they may be needed to fight infections.

It's far too soon to know if the discovery will actually lead to a new rheumatoid arthritis drug, said research team leader Dr. Eugene Butcher, assistant professor of pathology at Stanford and an immunopathologist at the Palo Alto Veterans Administration Medical Center.

But he observed in an interview that "if we could prevent lymphocytes from getting into rheumatoid joints, we would be able to shut down the inflammation and much of the disease process."

Butcher's co-authors on the *Science* paper are Dr. Sirpa Jalkanen, a postdoctoral fellow, Dr. Allan Steere, an associate professor on sabbatical leave in Butcher's laboratory from Yale University School of Medicine, and Dr. Robert Fox of the Scripps Clinic and Research Foundation in La Jolla.

Lymphocytes constantly circulate through the body in the bloodstream, migrating into tissues where they are needed to fight infection by passing through tiny specialized blood vessels called high endothelial venules, Butcher explained.

The researchers had been studying these blood vessels and the molecular receptor signals on their linings that tell white blood cells whether or not they can pass through. Only white cells with molecular receptor "keys" that fit can open the "locks" of the venules of different types of body tissues, he noted.

For example, in the lymph nodes, only white cells with a particular receptor can bind to and exit out of the venules. White cells with a different receptor can bind and exit through the venules that serve internal organs such as the intestine and appendix.

These distinctive lock-and-key receptor systems were originally discovered in studies of mice carried out by Butcher, Michael Gallatin and Stanford pathology professor Irving Weissman.

When Butcher and his colleagues went on to examine inflamed synovial tissue from four patients with rheumatoid arthritis, they found that yet another distinct molecular lock-and-key set was needed in order for white blood cells to enter the joint tissues.

This suggests that it might be possible to jam lymphocytes' ability to penetrate the joints without blocking their entry into other crucial body tissues.

A drug or monoclonal antibody that could seal off the joints from lymphocyte entry would be a "more specific and less toxic" kind of treatment than is currently available against rheumatoid arthritis, the researchers wrote.

One hitch is that the researchers do not yet know whether the joint tissue lock-and-key system is unique or whether it's shared by other sites of inflammation in the body.

"But it is clearly different from the recognition molecules of the lymph node system and the mucosal (internal organ lining) system," Butcher said, leading to the hope "that a drug or other agent can be found that will selectively block lymphocyte traffic into the joints."

The research was supported by grants from the National Institutes of Health, the Veterans Administration, and the Leukemia Society of America.

Men and women in the early stages of Alzheimer's Disease and experiencing memory loss, mood changes, confusion or social withdrawal are needed for a six-month drug study conducted by researchers at the Palo Alto Veterans Administration Medical Center and Stanford University.

Volunteers need to be aged 40 to 79 and in good health. They need not be veterans. Volunteers will receive free diagnostic evaluation as well as visits with medical professionals.

Individuals who suffer memory problems due to stroke, head injuries, cardiac disease, Parkinson's Disease or substance abuse are unsuitable for this study.

For more information, call Ken Fong at the Palo Alto VA Medical Center, (415) 493-5000, ext. 4778 or 4779.

News Release

Stanford Med. Center
JUL 18 1986
News Bureau

Iris Bernstein is 18 and wants to be a doctor. In the meantime, she spends her spare hours volunteering at the Palo Alto VA morgue as part of an unusual program that gives aspiring physicians a foundation in pathology before their first college class.

"This place for me is a magnet," she said. "People say 'Oh no, you work in the morgue. It's sick and gory.' But it's a fantastic working atmosphere and I'm learning a lot."

Leonard Kelley, supervisor of the morgue, said he started the cooperative program with Gunn High School 11 years ago. The program grew through word-of-mouth and now students from several high schools and colleges -- as well as medical professionals and others interested in medicine -- participate in the program.

Kelley said 85 percent of the students who go through the program become doctors and he has a lengthy list of successful alumni. This summer there are about eight volunteers in the program.

"They keep volunteering year after year and then go to medical school and end up physicians. One kid's been here seven years and is teaching the doctors," he said. "It's a good program, the best, but I'm prejudiced."

Kelley started a student volunteer program while working in the coroner's office in Oklahoma "because someone helped me. If those people hadn't, I don't know what I'd be doing." The program was so successful he brought it with him when he came to the Palo Alto VA.

-more-

New volunteers are introduced to the morgue slowly. In the first days they learn weights and measures, how to read charts, how to clean instruments and answer the phones. Eventually they learn how to dissect, recognize disease, draw blood, take cultures and assist with the actual autopsy.

The students react well to the program, Kelley said, despite the unusual setting, and he's yet to have a student faint during a procedure.

"Most of them have never seen anything dead, but it's how we deal with it. It's 'This is where they used to live and they've gone on,' " he said.

David Mayer, 26, has been a volunteer for seven years. He initially joined because of an interest in emergency medicine and a desire to learn more about anatomy. Now a college graduate with a degree in chemistry, he plans to go into pathology.

"You can't get this exposure to medicine anywhere else," he said enthusiastically.

Kara Ornstein, 17, a senior at Gunn High, is another volunteer. She works at the morgue 15 hours a week during the summer.

"I help with the body and do the sections and learn," she said. "I like the subject and I like to learn. The first time (I saw an autopsy) I had nightmares, but it does get better."

At 64, John Gonzalez is one of the program's oldest volunteers. He is an engineer at Stanford and has spend his summer vacation volunteering at the morgue for the past four years.

"If you really want to help your fellow man, and I plan to spend the last years of my life helping man, this is where it's at," he said. "Pathology is where you find the root of disease."

MONONUCLEOSIS SOMETIMES LEADS TO CHRONIC DAYTIME SLEEPINESS

STANFORD—

Infection with the virus that causes mononucleosis may cause disabling daytime sleepiness in some patients for years following the illness, report two Stanford University Medical School researchers in the July *Archives of Internal Medicine*.

The finding is a new clue in the search for causes of excess daytime sleepiness, a chronic condition that plagues more than half of all patients with sleep disorders, said Dr. Christian Guilleminault, associate director of the Stanford Sleep Disorders Clinic and professor of psychiatry in the School of Medicine.

Not all "mono" patients become sleepyheads, Guilleminault cautioned. But further studies and follow-up of patients who come down with mononculeosis could provide insight about who is at greatest risk, he predicted.

The researchers followed 12 young adults who complained of drowsiness after infection with Epstein-Barr virus, the cause of mononucleosis, for periods ranging from three to 12 years after initial infection.

All 12 patients fell asleep more quickly, slept longer at night, and napped more often during the day, compared to normal individuals in the same age group.

Although dextro-amphetamine, a stimulant, helped five patients stay awake longer, in general, attempts to treat the patients with medications were "mediocre," reported Guillleminault and his colleague Dr. Susanna Mondini, a postdoctoral fellow.

None of the patients regained normal sleep patterns during the follow-up period, the researchers reported, and for some, the excess sleepiness was disabling.

The condition of the three patients with the longest history of sleepiness worsened over time, and despite treatment with stimulant medications, they are currently unable to work because of their affliction, the researchers reported.

Three other patients modified their career goals to pursue less demanding professions as a result of the chronic sleepiness, they added.

How the viral infection could lead to chronic sleepiness is unknown, the researchers wrote. But the causative agent, the Epstein-Barr virus, has recently been linked to another chronic condition characterized by persistent fatigue.

The research was supported by grants from the National Institutes of Health.

HEAT AND MICROSCOPIC DRUG-FILLED CAPSULES COULD PROVIDE NEW APPROACH AGAINST BLADDER CANCER

STANFORD—

A new way of delivering tiny drug capsules directly to a tumor has yielded encouraging results in animals with cancerous growths, reports a team of Stanford University Medical School researchers.

The technique is appealing because it delivers high drug doses to a tumor, but should spare healthy tissues from the drugs' powerful effects, said Dr. J. Ronald Tacker, clinical assistant professor of medicine at Stanford Medical School.

The new method combines two still-experimental approaches to cancer: tumor bombardment by tiny blood-borne packets containing anti-cancer drugs, and heat.

Because the method involves heating the tumor, it is potentially most suited to localized cancers, Tacker explained. He and his colleagues are pursuing its possible effectiveness against bladder cancer, a malignancy that strikes 40,000 individuals each year in the United States.

The anti-cancer drugs are packaged in tiny envelopes of fat, called liposomes, which are injected into the bloodstream and carried throughout the body. Millions of the tiny spheres—each only slightly larger than a red blood cell—can be administered in a single injection.

At normal body temperature, the drugs remain sealed inside the liposomes. But at temperatures a few degrees above normal, the microscopic parcels melt, allowing the drugs to leak out.

"We think this might be a useful new way of treating bladder cancer, particularly for individuals who are not good candidates for surgery—the elderly or those with other underlying disease," Tacker said.

"The usual treatment for the disease is surgical removal of the bladder. But some people can't tolerate that major an operation," Tacker explained.

The strategy in bladder cancer patients would be to heat the bladder a few degrees above normal and give patients a liposome injection.

Tests in humans have already shown that the bladder can be heated above normal temperature with some beneficial effect against cancer, Tacker said. The heating is accomplished by means of a catheter inserted into the bladder, through which heated water is pumped into the organ.

In Europe, liposomes have been given to cancer patients, with no detectable adverse effects, Tacker said. They are made of naturally occurring lipids, found in many mammals, he noted.

In an article in the March issue of the *Journal of Urology*, the scientists reported that in test tube studies, their specially engineered heat-sensitive liposomes tightly encapsulate drugs while at body temperature; but the tiny containers disintegrate when they are heated up a few degrees, promptly releasing 80 to 90 percent of the drugs.

Tacker's colleagues in the study were Dr. James Bassett, chief resident in Stanford Medical School's division of urology, and Dr. Rodney Anderson, Stanford associate professor of surgery.

The researchers also reported that high levels of drugs could be concentrated in a tumor using this technique. In mice with cancerous growths, eight to 10 times more drug was concentrated in heated tumors as compared with those left at body temperature, Tacker said.

The highest concentrations were achieved when a drug called methotrexate, a standard anti-cancer medication, was enclosed in the liposomes. In similar tests, the researchers found that two experimental anti-cancer drugs packaged in liposomes could also be concentrated in the tumors, but at levels lower than methotrexate.

However, in further studies that will soon be published, Tacker has found that methotrexate is not as effective in actually shrinking tumors as one of the experimental drugs, JM8.

After further study, the researchers hope to conduct clinical trials of the heated-liposome therapy in humans sometime in the future.

"We would like very much to have a non-surgical method that treats the entire bladder in these cancer patients," Tacker explained. There is an 80 percent recurrence rate of bladder cancer following surgery, he noted. "If there is one malignancy, then there are usually other sites in the bladder that will turn cancerous," he explained.

Although radiation therapy is a second choice for bladder cancer patients, and traditional chemotherapy can be effective, both affect the entire body and can therefore cause severe side effects in healthy tissues.

KIDNEY STONE SURGERY CAN BE AVOIDED WITH SHOCK WAVES

Kidney stones, which affect about one in 10 Americans, can now be broken up using shock waves instead of surgery.

The new technique, called extracorporeal shock wave therapy or lithrotripsy, does not require surgery or, in most cases, hospitalization, says Stanford Medical Center's Dr. Duncan Govan. He is one of a small but potentially growing number of physicians who are making the treatment available. Since March 1985, the number of places nationally where the treatment is available has increased from seven to more than 60, he says.

Patients under general anesthesia lie in a tub of warm water while the force of up to 3,000 shock waves passes harmlessly through the tissue to blast kidney stones into fine, sand-like particles. Few side effects result, and in most cases patients can return to their regular activities following just a few days of rest at home.

Kidney stones, most commonly composed of calcium deposits, affect about one in every 10 American adults. They can be excruciatingly painful and can cause other complications. Until now they could only be surgically removed, Govan says.

HEADACHES USUALLY MINOR—BUT...

Headaches are uncomfortable although usually not dangerous, but a physician warns that when they persist for many days, it is time to see your doctor.

Dr. Michael Jacobs of the Stanford Medical Group says that headaches are most often caused by tension. Safe and effective cures include aspirin, hot or cold pads applied to the head or resting on one's back, he says.

But Jacobs adds that occasionally headaches can be a warning sign for more serious ailments. If the pain continues for many days without interruption, or if the headaches are accompanied by nausea, it is probably advisable to see a doctor, Jacobs says.

-more-

FAINTING USUALLY SIMPLE, BUT CHECK WARNING SIGNS

Fainting is a fairly common problem, but it sometimes can be a symptom of a more serious condition, cautions Dr. Michael Jacobs of Stanford Medical Group.

"If a person tells you they feel faint, have them lie down with their feet elevated above their head," says the Stanford Medical Center physician.

"Check the airways (nose and mouth) and feel their pulse. If they're breathing and their heart is beating, then cardiopulmonary resuscitation (CPR) is not needed, he says. Sometimes cold compresses applied to the person's forehead are helpful.

If the fainting is accompanied by chest pains, convulsions or severe headaches, or if the person is unconscious for more than one or two minutes, Jacobs recommends that an ambulance be called to transport the victim to a hospital emergency department.

Fainting is a temporary loss of consciousness that occurs from lack of oxygen carried to the brain through the blood. It can be caused by environmental conditions, such as being in a stuffy room or witnessing an upsetting event. Or it can be triggered by a serious physical condition, such as a heart attack which halts or slows down blood circulation. The scientific name of fainting is syncope.

CAREFUL DIET PROTECTS WOMEN AGAINST BONE DISEASE

Women should start protecting themselves against a common bone ailment called osteoporosis early in life by eating a calcium-rich diet and exercising, says a Stanford University physician.

Women should also refrain from smoking, which causes a drop in estrogen and potentially an earlier onset of menopause and osteoporosis, adds Dr. Robert Marcus, a Stanford faculty member who heads an aging study unit at the Palo Alto Veterans Administration Medical Center.

He says women need the equivalent calcium in a quart of milk per day until age 50, and a quart and a half of milk daily after that to avert calcium loss in the bones.

Lack of calcium in the diet results in a woman's body cannibalizing bones to maintain sufficient calcium levels in the blood. This leads to the fragile bones characteristic of osteoporosis. Prevention should begin in the teen years or even earlier, Marcus says.

The physician says that calcium is found not only in milk, but in all dairy products, as well as chicken bones and dark leafy vegetables.

Another useful way to avoid osteoporosis is regular exercise to build stronger, denser bones, says Marcus.

ROUTINE X RAYS SHOULD BE HALTED, DOCTOR SAYS

Routine chest X rays, often given as part of a periodic health examination, may do more harm than good and should be stopped, says a Stanford physician.

Dr. Eugene D. Robin, professor of medicine, says the tests may be more harmful than previously suspected. Risks include exposure to radiation and a relatively high rate of inaccuracy which can suggest inappropriate or unnecessary treatment, he said. In addition the procedure is costly.

While evidence suggests that routine X rays can uncover lung cancer before symptoms occur, "there is no evidence to suggest that this early diagnosis in any way improves the chances of recovery or prolonged life for the patient."

The Food and Drug Administration's National Center for Devices and Radiological Health recently recommended that routine X rays not be required solely for hospital admission, "often for conditions having nothing to do with suspected lung or heart disease," Robin says. Other common uses—which Robin would like to see checked—include preemployment physicals or as a part of an annual physical.

Robin said there is no evidence that routine chest X rays provide information that ordinarily results in more benefits than risks.

The physician suggested that patients might be provided with a written record or diary of all X-ray exposure during their lifetime to alert them and their physicians to cumulative radiation risk.

"Physicians shouldn't order routine chest X rays and the public shouldn't request them from their physicians," Robin says.

EMERGENCY DEPARTMENT PLEA—CARRY YOUR PRESCRIPTIONS WITH YOU

Persons should try to bring current medication or copies of their prescriptions with them when they have to visit their hospital's emergency department, says a Stanford doctor.

"We can learn a lot about a patient from what drugs he is taking," explains Dr. Ric Martinez of Stanford University Hospital's Emergency Department. He suggests that persons can be prepared for emergencies by carrying copies or a list of their presciptions in their billfolds or purses.

Persons showing up in the Emergency Department are often unconscious or inconherent and thus incapable of communicating viatal information. Also, the doctor is usually seeing that particular patient for the first time, unlike a family physician who has records and knows his or her patient's special needs.

Knowing what drugs a person has been taking alerts doctors to a patient's special medical needs. Often it helps the physician to avoid ordering a drug which might react negatively—or perhaps dangerously—with the patient's regular medication. From medications, physicians can deduce the patient's medical problems, including high blood pressure, cardiac disease, diabetes or ulcers.

SIMPLE PRECAUTIONS IN PREGNANCY PREVENT RISKS OF TOXOPLASMOSIS

A few simple precautions during pregnancy could help mothers-to-be from passing on to their unborn infants a dangerous infection called toxoplasmosis, says a Stanford Medical School professor.

The infection, called toxoplasmosis, is usually harmless and in fact about 50 percent of the population have the toxoplasma organism without even knowing they're present, explains Dr. Jack Remington, professor of medicine.

But if the infection is acquired during pregnancy, the parasite may pass to the developing and otherwise unprotected fetus. This ultimately can cause mental retardation, epilepsy, or blindness later in life, Remington says.

Remington suggests just a few simple preventive steps pregnant women can take to avoid the potential danger to their unborn children:

- avoid eating raw or rare meat
- carefully wash all raw vegetables before eating
- wash hands thoroughly after handling raw meat or vegetables
- wear gloves when working in the soil or gardening
- avoid contact with cat feces and cat litter boxes

Remington adds that the danger to fetuses occurs when a pregnant woman becomes infected for the first time **during** pregnancy.

About 25 percent of women in the child-bearing age group already harbor the organism in their bodies before becoming pregnant. In them, the infection poses no threat to the unborn child because it is kept in check by the mother's immune system, he says.

CHILDPROOF CAPS CAN BE NEEDLESS NUISANCES

Childproof caps on medications save hundreds, perhaps thousands, of children's lives every year, but they can be a nuisance—and even a handicap—for many adults, says Robert Miller, pharmacy director at Stanford University Hospital.

"A senior citizen with arthritis, for example, might find it painful and confusing to handle a childproof cap," Miller explains.

Either the physician or the patient can specify an adult cap. The request can be put right on the prescription by the doctor, or the patient may simply ask the pharmacist to use an easy-open cap. Miller adds that as a precaution, some pharmacists might ask the patient to request the easy-open caps in writing.

Miller cautions, however, that families with children or elderly persons who have contact with children—such as grandparents—continue to use the safety containers.

"The evidence is just so overwhelming that childproof caps save lives," he says. Accidental drug overdose deaths among children have dropped dramatically since child resistant caps were mandated in 1972, Miller says.

NEW VACCINE PROTECTS CHILDREN FROM SERIOUS BACTERIAL DISEASE

Children aged 2 to 5 should receive a newly available vaccine which protects against hemophilus influenza type B disease, says Dr. Fernando Mendoza, assistant professor of pediatrics at Stanford.

"This is the first time that we have had a vaccine available for this serious infection, which afflicts one out of 1,000 of all U.S. youngsters between 2 and 5," says Mendoza. The infection, he explains, has been the leading cause of bacterial meningitis in young children and can also lead to pneumonia and a variety of other more serious illnesses.

"Children, such as those in day care, who are exposed to a lot of other youngsters may be especially at risk, but all parents of children in the 2 to 5 age group should ask their pediatrician about the vaccine," says Mendoza.

The vaccine appears to offer less protection to children less than 2 years old, but children in day care might be considered for the vaccine as young as 18 months, he says.

The vaccine, may produce mild fever in some children but has been proven safe and effective during extensive testing prior to general release in this country in the first part of 1985, says Mendoza.

LATE NIGHT SNACK NO ANSWER FOR NIGHTTIME SOLACE

A late night snack might be a satisfying way to end the day, but it can be hazardous to health if eaten regularly, says Dr. Keith Taylor, a gastroenterologist at Stanford Medical Center.

Persons who repeatedly go to bed and fall asleep too soon after eating may be asking for complications caused by excess acid production in the stomach, says Taylor.

To avoid the problem, Taylor recommends that persons eat not less than two to three hours before going to sleep at night. The same advice applies to persons who already have gastric (stomach) or duodenal (upper intestinal) ulcers.

Digestion is slowed down during sleep, along with just about every other body function. "Therefore, when you eat before sleeping, your stomach produces acid which wouldn't normally be produced," Taylor explains.

Some of the acid will wash back into the lower end of the esophagus (the gullet), if you are lying down, often producing irritation and even ulceration, as well as acting on ulcers already present in the stomach or duodenum.

A decade and more ago, physicians would recommend milk as a way to line the stomach, neutralize the acid and help heal ulcers.

"But we found that was actually harmful. Milk, of all the things we eat or drink, is unfortunately for would-be sleepers, one of the best stimulators of acid production," Taylor explains.

LIABILITY ISSUE THREATENS DEVELOPMENT OF AIDS VACCINE, SCIENTIST SAYS; URGES CALIFORNIA LEGISLATURE TO ACT

STANFORD—

"Without some form of liability protection, California biotechnology firms, now in the forefront of AIDS research, may not be able to develop an AIDS vaccine," a Stanford University scientist and member of the Institute of Medicine's special panel on vaccines said Tuesday, July 8.

Assembly Bill 4250 to encourage the development of an AIDS vaccine is moving through the California legislative process in Sacramento, but it has captured the attention of the Trial Lawyers Association (CTLA) which so far has been successful in winning key amendments that weaken it, said Dr. Thomas C. Merigan in an interview.

The bill will be heard by the Assembly's Ways and Means Committee tomorrow, July 9.

At issue is not just an AIDS vaccine but whether society's need for vaccines in general is compelling enough to warrant that kind of an effort on the part of state government to reduce manufacturers' exposure to liability, said Merigan, a professor of infectious diseases at Stanford University School of Medicine.

Merigan, who supports AB 4250, said that "without some form of liability protection, new vaccine development will be seriously hampered in the state."

Only a few biotechnology companies are now willing to take risks, Merigan added, and most of them are doing it against the wishes of their business people.

More than a dozen groups, including the California Manufacturers Association, Association of California Life Insurance Companies, Inland AIDS Project and two Northern California-based firms, Genentech, Inc. of San Francisco and Chiron, Corp. of Emeryville, support the liability legislation. Chiron, using the processes of genetic engineering, recently developed the long-awaited hepatitis B vaccine expected to be approved soon by the Federal Food and Drug Administration.

Merigan is a member of the committee on public-private sector relations in vaccine innovation of the Institute of Medicine of the National Academy of Sciences. The committee, composed of scientists, physicians, lawyers and economists recently issued an ominous warning on the current situation in a report titled *Vaccine Supply and Innovation*.

"There is cause for grave concern over the nation's vaccine supply," said the committee, listing the liability issue as a major deterrent.

Noting that the only supplier of vaccine products is private industry, the committee recommended the establishment of a federal commission to anticipate and resolve problems in vaccine development, supply and use, including the development of a compensation system for vaccine-related injury.

Merigan said AB 4250 would make California a leader in the nation in dealing with this issue in a socially responsible and just manner.

-more

7-8-86

The bill, authored by Assemblyman John Vasconcellos, D-San Jose, would remove the AIDS vaccine from the strict products liability doctrine by declaring it an "unavoidably dangerous" product, for which the public interest in its availability outweighs strict liability issues.

The bill creates an AIDS Vaccine Victims Compensation Fund to pay for all direct medical costs and up to $550,000 in noneconomic losses, and a special fund whereby the state guarantees purchase of one million doses of an AIDS vaccine at a cost of up to $20 million.

In California the "unavoidably dangerous" exemption is a recent development in *Kearle v. Lederle Laboratories* case. A state appelate court in 1985 ruled that the oral "live" polio vaccine was an "unavoidably dangerous" product and exempt from strict liability because the product was intended to provide an exceptionally important benefit that made its availability to the public highly desirable.

In essence, its proponents say, AB 4250 would codify the "unavoidably dangerous" doctrine spelled out in Kearle. The bill cleared the Assembly Judiciary Committee last month, but not before the original language, "dangerous," was changed to "unsafe" by an earlier assembly subcommittee at CTLA's urging.

"They (the trial lawyers) want to preserve the tort system," said Merigan. "They want to be sure that each individual can claim a special circumstance for a given liability.

"I can understand why we have tort law and what concerns the lawyers. Yet spreading the cost of risk throughout the society is the best approach to deal with vaccines because we will never have an absolutely safe vaccine.

"Whenever you try a new vaccine, you're not only taking it to protect yourself, but also to prevent the infectious agent from spreading in the community. One can argue the community has a stake in your being vaccinated. And certainly this California bill has the advantage of spreading the cost of risk to the whole population which is ultimately benefitting.

"You have both control of risk for the manufacturer, and a commitment to the rights of the individual."

Merigan compared California's effort to the Scandinavian approach where the state puts aside money and a commission decides whether an adverse reaction is due to the vaccine, and if so the individual who has made a personal sacrifice for society is compensated in a reasonable manner.

"It would be tragic," Merigan said, "if as a nation we overreact and stop using vaccines or withdraw from vaccine production because of some rare adverse effects while overlooking the benefits to the majority. When people in Great Britain did just that recently there was a recurrence of disease previously controlled by vaccines, including new cases of paralytic polio."

The Institute of Medicine report cites the difficulties of trying to find a cause-and-effect relationship where vaccines are concerned. As an example, it cites the pertussis (whooping cough) vaccine which has been the object of a flood of law suits because it is alleged to have caused neurological defects and sudden infant death in children.

"The appearance of one of these conditions shortly after vaccination may be difficult to prove or disprove in an individual case," according to the report. "Many of the alleged severe injuries from pertussis vaccine, such as infantile spasms, have not been found to be caused by the vaccine.

"This distinction between temporal association and causation may not be grasped readily by lay jurors and others who are unaccustomed to dealing with the concept, and most explanations are based on complex epidemiology that is even more difficult to comprehend.

more

"Therefore, juries faced with a seriously damaged child and agonized family are understandably sympathetic to the plaintiffs."

The committee said "serious deterrents to vaccine manufacturing in the United States arise from the unpredictable nature of the current liability situation. And it warned that most major vaccines are available only from sole manufacturers who for any reason could withdraw from the market.

Vaccine stockpiling, the committee said, can do little to guard against the interruption in the supply of a vaccine, and there are no contingency plans to meet this situation.

Reliance on foreign manufacturers does not offer a practical solution either, the committee added, because of differing regulatory requirements, political considerations, and language barriers that often make the resolution of technical issues difficult.

The committee listed other deterrents to vaccine innovation—among them the complexity of development, production and quality control and the cost of research in relation to anticipated sales.

Concluding that all vaccines have risks, "even when they are manufactured according to licensed procedures and administered in accordance with recommended medical practice," the committee said:

"Most vaccines are promoted or required by the government for the public good; therefore, the committee believes that society has a responsibility to develop some means of compensating those those with vaccine-related injuries.

"Those who respond to the government's promotion of or legal requirement of vaccination convey benefits to other members of society because they reduce the risk of disease in the community.

"If vaccination results in an injury, the injured individual should be certain of receiving rapid and adequate compensation.

"The common law tort system cannot be relied on to provide such compensation because each claim requires an extended, costly and complex procedure to establish liability."

Although these problems exist, the committee also noted that the prospects for new and safer vaccines have never been brighter. They stem primarily from advances in genetic engineering and the ability to define the protein components responsible for inducing immunity.

"Researchers are presently trying to identify their precise chemical structures and to synthesize them with new technology," Merigan said. "We may soon have the capability of replacing existing vaccines that contain superfluous components with safer and more effective vaccines of higher specificity."

STANFORD TO BEGIN HEART TRANSPLANTS IN INFANTS

STANFORD—

Stanford University Medical Center, the world's leading heart transplant institution, has taken formal steps to begin heart transplantation in neonates—babies in the first six to eight weeks of life—who have critical heart disease that is otherwise untreatable.

The transplantation will begin whenever there is a candidate and a suitable donor heart available, said Dr. David Baum, chief of pediatric cardiology. He said there are no neonates specifically waiting for transplants at Stanford.

The youngest patient to receive a heart transplant at Stanford so far was 2 1/2 years old at the time of the operation. However, Baum noted that Stanford has had a continuing program of heart transplantation in young people—those under the age of 19 years.

"Heart transplants have been done in this group for about 12 years," he said. "The program has been very successful, and with evidence of increasing need plus the fact that we were learning more and more about heart transplantation in young people, the age group gradually has been extended farther and farther back. This (the transplant decision) simply represents another extension."

Baum made it clear that the recent widespread publicity about infant heart transplants had nothing to do with the Stanford decision. The decision to include the neonatal period was made several months ago and preparations have been ongoing since then, he said.

"One of the reasons we haven't done it (a neonatal heart transplant) as yet is we have been taking pains in making the necessary preparations," he said. "We wanted to be sure that we had taken into account every possible recognized situation to assure the success of the transplant and to protect the child and his or her loved ones."

For that reason, Baum said, members of the cardiac transplant team had their plans reviewed by the medical center's Human Subjects Committee, a multidisciplinary group that has the responsibility to look after the rights of human subjects used in research.

The neonatal transplants could be considered experimental procedures, Baum said, because of the large number of unknown factors, such as how tiny bodies will react to immunosuppressant drugs. He noted there is almost no human experience in performing such operations.

Cardiac transplant team members also consulted with the medical center's Ethics Committee before deciding to go ahead with the procedure. "We were interested in getting as much insight as possible from others whose opinions we respect," Baum said.

He noted Stanford's role of leadership in heart transplantation, "not only with cardiac transplantation in general, but with cardiac transplantation in the very young." That leadership role, he said, was an additional factor in the decision to expand the age limits on transplantation to meet a growing need.

Dr. Norman E. Shumway, heart transplant pioneer and chairman of the Department of Cardiovascular Surgery, predicted in an interview last December that there would be increasing numbers of children receiving heart transplants.

Discussing the Stanford patients under 19 who have received transplanted hearts, he said, "The results seem to be better in the younger age group. We're very interested in looking into that."

HOW TRAUMA CENTERS MAKE THEIR IMPACT ON PATIENT CARE

STANFORD—

One patient was a woman whose legs were crushed when she was hit by a car and thrown into a drainage ditch; another was a man hit by a motorboat and flown to the hospital by helicopter while bleeding profusely; a third crashed into a tree on his motorcycle and had multiple internal injuries.

All of those patients survived, but it's possible—even probable—that all would have died if they had not been taken to a trauma center where they could receive immediate surgical attention.

On the other hand, a 13-year-old boy whose spleen was damaged in a bicycle accident *didn't* have an operation for essentially the same reason: He was brought to a trauma center where a pediatric surgeon was immediately available to determine that he would be better off if the spleen were not removed.

All of those cases involved the Trauma Center at Stanford University Hospital, but they could have taken place at another trauma center similarly staffed and equipped. They illustrate the impact of this new concept on patient care.

Trauma centers are a relatively new concept for the San Francisco Peninsula. Santa Clara County got its first centers this year, and one has yet to be established in San Mateo County.

They are being developed more and more around the country, however, as medical authorities become more aware of their life-saving potential. The Stanford experience in just a few months is evidence of that potential. So is a 1982 study by the American College of Surgeons that said 42 percent of emergency room deaths could be prevented by proper trauma care.

What makes trauma centers different from the usual community hospital operations is the sheer volume of expert medical care available to each patient. At Stanford, a 13-member trauma team is on duty 24 hours a day, seven days a week.

The key member of the trauma team is the surgeon. He or she is the team leader and the first person to see the patient. That means, of course, that the trauma surgeon decides if surgery is necessary—and is immediately available to perform it.

The Emergency Department is staffed 24 hours a day with emergency medicine physicians who supervise pre-hospital care and direct paramedics as to which cases go to the Trauma Center.

A closer examination of the cases mentioned earlier shows how the system works.

- Berthella Dancy, 39, of Mountain View, is the woman hit by a car while jogging and thrown into a drainage ditch. She owes her life to several helpful individuals as well as the special medical attention she received.

One bystander reached her side immediately after the accident and helped hold her head out of the water. Other bystanders called the paramedics and two emergency medical technicians from Lockheed Missiles and Space Corp. helped get her out of the ditch and into an ambulance.

By the time she got to Stanford Hospital, Dancy was in shock and in desperate need of fluid resuscitation. "She needed the expertise of a whole group of surgeons," said Kathy Canevaro, trauma nurse coordinator. "General surgery and orthopedic surgery had to be coordinated and pulled together in a short time."

Dancy eventually had multiple operations and lost her right leg below the knee. But she lived.

- Stephen Dusse, 21, was riding a motorcycle when it careened into a tree at 40 miles an hour. Because he was wearing a helmet, he had no head injuries. But he suffered major injuries to his liver and one kidney.

"This is the sort of patient trauma centers are particularly helpful for," said Dr. John Collins, director of the Stanford trauma program. "The kind of patient who dies soon after arrival in the emergency room. His injury would have caused him to bleed to death if he hadn't been operated on almost immediately."

• Kevin Fuller, 23, was a long way from medical help when his boat was hit head-on by another boat in Calero Reservoir south of San Jose. By the time friends got him out of the water he was losing blood at an alarming rate.

Fortunately, a Stanford Hospital Life Flight helicopter was able to land at a school nearby and within minutes, Fuller was at Stanford Hospital. He was rushed into surgery for the first of a series of operations.

• Then there was 13-year-old John Polstra. He was in a bicycle accident in which he struck his chest and upper abdomen, injuring his spleen. In the past traditional practice of medicine, his spleen would have been removed. But modern pediatric medicine makes every attempt to save the spleens of children and a pediatric surgeon was available at Stanford to determine that an operation was not necessary. John recovered without an operation.

As that last example shows, the trauma team makes use of all the expertise available in the hospital when it is necessary. In the majority of cases, however, there are few medical problems beyond the knowledge of the 13 members of the team.

At Stanford, the trauma team consists of a senior trauma resident in surgery, the attending surgeon and an attending emergency medicine physician as well as a physician from anesthesia. Others on the team include a trauma resuscitation nurse, a patient nurse, an operating room nurse, a respiratory therapist, a pharmacist, an X-ray technician, a nursing assistant, a transfusion aide and a phlebotomist.

The arrival of a trauma patient brings all of the team members into the trauma room in the Emergency Department, all with specific tasks. To a non-medical observer, it is an impressive display of the kind of medical care that can be marshaled rapidly for critically injured patients.

Not all of the patients brought to the trauma center are critically injured. In fact, some have been able to leave in a few hours after little or no treatment.

Those patients, however, *could* have been injured critically. They were brought to the trauma center because paramedics were taking no chances. The patients had registered in the danger area on a "trauma score," which is based largely on the type of accidents known to cause severe injury.

"This is one of the most important groups of patients in any trauma system as it is in this group of seemingly well patients that many of the avoidable deaths occur," Collins said.

"Specialized knowledge and facilities and a high index of suspicion are required to properly evaluate these patients. Many will in fact prove to have no serious injuries and the system may thus appear at times to be wasteful. But only careful and expert evaluation can distinguish the not seriously injured from the deceptively intact patient with a disastrous hidden injury."

A fall of more than 15 feet is one of the high-risk accidents. Others are a motor vehicle accident at more than 25 miles an hour without a seat belt, one in which it took more than 20 minutes to extricate the victim from the vehicle, one in which the steering wheel is bent by the impact with the driver's body, or one in which the vehicle rolls over.

Other factors that will increase the trauma score are penetrating wounds, major burns or accidents involving potentially more fragile individuals such as infants or older adults.

The paramedics in the field work under very specific protocols. Those patients who have obvious significant injuries are transported immediately to trauma centers, with paramedics giving emergency care at the scene and en route to the hospital.

In evaluating patients who don't appear to be significantly injured, the paramedics communicate with the base station hospital. The emergency physician and the mobile intensive care nurse screen those patients. Any patients with significant chance of a major injury are taken to a trauma center for evaluation.

The emergency medicine specialist physician, responsible for all patients in the Emergency Department, works with the trauma surgeon in evaluating the patients, ensuring that patients who need aggressive resuscitation and surgery are identified and treated promptly.

Often, the trauma team deals with more than one patient at a time, and the team members have to treat several patients while back-up teams are being summoned.

MITCHELL APPOINTED SUMC DIRECTOR OF DEVELOPMENT

STANFORD—

David L. Mitchell has been appointed director of the Stanford University Medical Center's Office of Development, Henry Riggs, University vice president for development, announced Monday, June 30.

The 36-year-old Mitchell will succeed John Ford who last March assumed new duties as associate vice president for development at the University. Mitchell's appointment is effective immediately.

Riggs said the appointment was made following a search, both within and outside Stanford, for an individual with strong leadership track record.

"David brings to this new position outstanding fund-raising experience gained at Stanford and several other universities," Riggs said.

Mitchell has been at Stanford since 1984. He has directed the university's major gifts program, staff and volunteer training, and coordinated the fund-raising campaign for a $30 million biology building.

During the several months of transition, Ford will continue to devote a portion of his time to medical development as Mitchell assumes his new responsibilities, Riggs noted.

He said that the Medical Center's $197 million fund-raising agenda is now mid-stream, "and we want to be certain that the momentum associated with a number of projects and solicitations is well maintained."

Paul Edwards, who served as acting director of the office for the past four months, will return to his duties as director of development of the Stanford University Hospital, Riggs said.

Prior to coming to Stanford, Mitchell had served as assistant chancellor for development at the University of California, San Francisco and vice president for Development for the UCSF Foundation. He also held key fund-raising posts at Northwestern University, and other schools.

Mitchell pursued a master's degree in management at Northwestern University's J.L. Kellogg Graduate School of Management and received his bachelor's degree from Lawrence University in Appleton, Wis.

STUDY SEEKS SIGNALS OF HEART IRREGULARITIES AMONG RUNNERS

STANFORD—

Serious runners are being sought by Stanford Medical Center researchers for a study of the physiological mechanisms that may cause abnormal cardiac rhythms among joggers and runners.

Although several studies have documented the health benefits of exercise, the dangers of sudden death during exercise also have been widely publicized—most notably by the death of author/runner James Fixx.

The intent of the study, according to Susan Garay of the Stanford Center for Research in Disease Prevention (SCRDP), is to measure physiological differences in runners by age groups to see if there are signals that might warn of cardiac problems during vigorous exercise.

Male runners are needed in two age groups, one 20 to 30 and the other 55 to 65. All volunteers must run at least 20 miles a week and have participated in at least two 10-kilometer races in the last year. The 20-30 year olds must have a 10-kilometer time of 35-41 minutes; the 55-65 year olds must have a 10-kilometer time of 45-51 minutes. The runners also must be healthy, non-smokers and free of known cardiovascular disease.

Drs. Peter Wood and William Haskell are the principal investigators on the research, which is a project of the SCRDP.

Volunteers will be given two treadmill tests at different times: one will be a test of maximum oxygen consumption or aerobic capacity and the other will be a simulated 10-kilometer run.

Blood pressure, cardiac rhythm and serum free fatty acid levels will be measured during and after the tests. In particular, volunteers will be tested for levels of catecholamines, chemicals released into the blood stream by the nervous system that influence heart function.

Catecholamine levels are known to increase with age and intensity of exercise. However, little is known about the effect of vigorous exercise on catecholamines in older men.

A second objective of the study is to determine whether vigorous exercise is associated with cardiac arrhythmias at significantly higher rates in older runners than in younger runners. Since the prevalence of heart disease increases with age, older runners may be at greater risk of cardiac abnormalities while running than younger runners. However, this is another area lacking specific data.

In addition, the study will attempt to determine the correlation between levels of free fatty acids and exercise. Research with animals has shown a relationship between excess levels of free fatty acids and heart irregularities.

All participants will receive free cholesterol, aerobic capacity, electrocardiogram and blood pressure information.

Male runners in the targeted age groups who are interested in participating in the study should call (415) 725-5311, from 9 a.m. to noon, Monday through Friday.

Veterans
Administration

News Release

Stanford Medical Center
JUL 2 1986
News Bureau

July 1, 1986

The Veterans Administration's most wide-sweeping changes in health care eligibility took effect July 1, two months after Congress passed Public Law 99-272. The law will require some veterans -- for the first time -- to pay for a portion of their VA health care, while quaranteeing other veterans a hospital bed.

Under the new law, the VA is required to provide hospital care to service-connected and lower-income veterans. Veterans with higher incomes will will receive care on a space-available basis and also may have to agree to pay a $492 deductible every quarter.

These new standards replace the old system where service-connection and age -- not income -- were the basis for determining eligibility.

Specifically, the law establishes three eligibility categories. Category A includes service-connected veterans, former prisoners of war, veterans exposed to Agent Orange or ionizing radiation while in the service, a veteran receiving a VA pension and veterans of the Spanish American War and WWI. Veterans who earn less than $15,000 if single and $18,000 if married also are in this category. These veterans are quaranteed free hospital care. Outpatient care and nursing home placements may be provided on a space-available basis.

-more-

Veterans in Category B earn between $15,000 and $20,000 if single, and between $18,000 and $25,000 if married. These veterans will receive care on a space-available basis.

Category C veterans earn more than $20,000 if single and more than $25,000 if married. These veterans receive care on a space-available basis, but also must agree to pay a deductible. Veterans in this category who do not agree to pay the deductible will not be eligible for care from the VA.

Veterans receiving inpatient care prior to July 1 will not be affected until their current treatment is completed. Veterans receiving outpatient treatment prior to July 1 and needing additional care also will not be affected immediately.

For more information, call Michael Brown or Kenneth Swasey, at 493-5000 exts. 5633 and 2334.

NEW ELECTROPHYSIOLOGY LABORATORY OPENS AT STANFORD

STANFORD—

A major new electrophysiology laboratory to aid heart specialists in their efforts to prevent cardiac arrest was opened in June at Stanford University Hospital.

The laboratory, described by Dr. Charles Swerdlow as "state-of-the-art," is one of the first components of Stanford Hospital's $114 million modernization project to be completed. It features equipment worth $550,000.

Swerdlow, director of the laboratory and assistant professor of cardiology, said, "The equipment is compact and easy to operate and there's a computerized switching system that allows us to switch between instruments measuring different areas of the heart."

Dr. Donald Harrison, head of the Division of Cardiology at the Stanford University School of Medicine, said, "The problem of sudden death because of abnormal heart rhythm disturbances is one of the most important challenges facing cardiologists today."

More than 150,000 patients under 65 die suddenly of these electrical disturbances in the United States each year, Harrison said.

"The number of people with abnormal rhythm seems to be increasing," he added. "The reason is more people with advanced heart disease are living because of other advances in cardiology."

Stanford's heart specialists have pioneered in the development of techniques for identifying patients at high risk for sudden death, Harrison noted. The research has begun to determine the most effective drug therapies and devices for preventing arrhythmias.

"The new laboratory will provide equipment to match these developments," Harrison added.

Cardiac electrophysiology is a technique for recording electrical signals from inside the heart to diagnose arrhythmias.

The normal heart of a resting individual beats steadily at about 70 to 80 times a minute in response to electrical signals within the heart. Any interruption of those signals can produce an arrhythmia, but a lot of arrhythmias are mild and pose no major threat.

Some people, however, have serious arrhythmias—those in which their hearts race wildly out of control or are unable to function properly in pumping blood. Those arrhythmias can be fatal if left untreated.

Treatment involves three basic approaches: the use of drugs, surgery, and implantation of devices that will stop arrhythmias.

Before any treatment, however, it is necessary to have an accurate diagnosis, a precise determination of the area of the heart that is causing the problem. That diagnosis is the function of electrophysiology.

The first step in electrophysiology is the insertion into the heart of long, thin tubes called pacing catheters. They are inserted through veins and arteries in the groin or collarbone areas, then positioned in specific areas of the heart by physicians using X-ray visualization.

Once in place, the catheters can alter a heart beat and help physicians diagnose an arrhythmia that can't be diagnosed by other means. They can also be used to reproduce an arrhythmia in patients who have had previous attacks, allowing physicians to evaluate the effectiveness of drugs or other antiarrhythmic treatments.

Swerdlow said Stanford physicians are also using new catheter techniques that avoid the need for surgery or life-time drug treatment for some patients with "supraventricular arrhythmias."

"Electrode catheter ablation" is the name for the new treatment, which Swerdlow described as "high energy electrical shocks delivered to the heart to produce a small area of localized damage," which blocks electrical conduction.

Such treatment can be used only in specialized cases. Many patients still need regular surgery, which involves either removing or freezing the area of the heart that is causing the problem. Swerdlow noted that surgery is particularly effective in cases of Wolff-Parkinson-White Syndrome, in which patients are born with extra electrical pathways and can suffer arrhythmias when heart impulses travel along those extra routes.

Swerdlow said there is "virtually certain cure" of Wolff-Parkinson-White Syndrome by surgery if the electrophysiological evaluation is accurate.

Supraventricular arrhythmias are called that because they start in the area of the heart above the ventricles. More common are ventricular arrhythmias, originating in the ventricles in the lower part of the heart. They are frequently the result of a heart attack that has damaged the tissue.

Surgery is equally effective on ventricular arrhythmias, but doctors prefer drugs if they are effective because they are less destructive to the body. "No anti-arrhythmia drug is effective uniformly, however, and all have some side effects," Swerdlow said.

Implantable devices that control arrhythmias are "generally a last choice for treatment," Swerdlow said, "because they only interrupt arrhythmias after they've started, rather than prevent their occurrence."

Swerdlow pointed out that the electrophysiology laboratory is "only one aspect of the total care of patients who have arrhythmias. That care includes better outpatient diagnostic equipment, cardiac surgery and a dedicated staff of nurses who specifically help care for arrhythmia patients."

VOLUNTEERS SOUGHT FOR HYPERTENSION RESEARCH

STANFORD—

Researchers at the Palo Alto Veterans Administration Medical Center are seeking volunteers for a study of metabolic changes that may be associated with hypertension, or high blood pressure.

The researchers are exploring the possibility that some of the metabolic changes may be risk factors for coronary artery disease.

Volunteers with hypertension are needed for a study of the possible similarity between hypertension and diabetes mellitus. Volunteers with normal blood pressure are also needed, to test the effects on blood fats of clonidine, a drug commonly used to lower blood pressure.

The studies will take place at the Aging Study Unit at the VAMC, under the direction of Drs. Gerald Reaven, Brian Hoffman, Art Swislocki and their associates. Reaven is professor of medicine at the Stanford University School of Medicine.

Those interested in participating in the study are asked to call (415) 493-5000, ext. 4572, between 9 a.m. and 5 p.m., Monday through Friday.

HEART, KIDNEY RECIPIENTS TELL OF LIFE WITH TWO TRANSPLANTED ORGANS

STANFORD—

Two men who are apparently the world's only living recipients of both heart and kidney transplants issued a joint plea for public awareness of the need for organ donations at a news conference at Stanford University Medical Center Friday, Aug. 29.

The two are Mark Williams, 29, of Mountain View, and Louis Bonesio, 52, of Gilroy.

Williams had a heart transplant—his second—at Stanford on July 17 and a kidney transplant on July 19. Both organs came from the same donor, a 23-year-old man killed in a motor vehicle accident in Santa Rosa. Williams' first heart transplant was on Aug. 4, 1982.

Bonesio received his heart at Stanford 12 years ago, on May 11, 1974, and had a kidney transplant on July 29, 1985, at the University of California-San Francisco.

The surgeon who performed both kidney transplants, Dr. Nicholas J. Feduska of UCSF, also spoke at the news conference. He described the cooperation between the two medical institutions that brought him to Stanford for Williams' transplant because Stanford is not doing kidney transplants at this time.

Feduska, who had made calls to other medical centers performing kidney and heart transplants, said there were no records of any other survivors of the joint transplantations.

Two Stanford physicians, Dr. Sharon Hunt, clinical associate professor of medicine, and Dr. Vaughn Starnes, chief transplant resident, described some of the medical complications that brought Williams back into the hospital.

Williams' kidneys were deteriorating because of toxicity caused by the use of cyclosporine, an immunosuppressant drug he had to take to keep his body from rejecting his first heart transplant. Then he suffered a heart attack and was very near death when the donor organs became available and made the double transplant possible.

Hunt said cyclosporine is a "double-edged sword" because it is necessary to avoid the rejection of organs but it can have adverse side effects. However, she said physicians have become "a lot smarter about using it" since Williams was first put on the drug and she thought he would not encounter the same problems with its use now.

Williams and Bonesio both said they have no regrets about their operations and have enjoyed a high quality of life.

"I can do anything anyone else can," said Williams, pointing out that three weeks before his heart attack he had been on a white water rafting trip.

Both men, as well as the three physicians, spoke of the need for organ donors for other potential transplant recipients.

"I want to do well because someone else gave me a chance," Williams said.

13-POUND BABY BORN AT STANFORD HOSPITAL

STANFORD—

Frances Christine Petersen is only two days old, but she's already made a big impression on people.

A very big impression. Frances checked into the world at 13 pounds, 1 ounce, and sent nurses at Stanford University Hospital scurrying for the record books.

Although Frances' weight is about three pounds below the world record, she's the biggest baby in the memory of Stanford Hospital employees. She's also the biggest baby delivered by Dr. James Stickler in 28 years of medical practice and the biggest her pediatrician, Dr. Richard Green, has ever had as a patient.

Stickler and Green are both physicians at the Palo Alto Medical Clinic, where Frances' mother, Roxanne, works as a nurse. Being a nurse, Roxanne was prepared for a big baby—but not that big. "I expected about 11 pounds," she said.

The amazing thing about Frances' birth to nurses at Stanford Hospital was that it was a regular birth, not Caesarean. And it wasn't a delayed birth. "She was actually four days early," her mother said.

Roxanne and her husband, Samuel, have two sons, both of whom were robust infants weighing more than 9 pounds at birth, even if they didn't measure up to their sister.

The Petersens live in San Jose, not far from her parents, Franki and Marvin Rhodes of Campbell. Frances, who is named for her grandmother, is the Rhodes' 22nd grandchild, but she won't hold the title of youngest grandchild for long. Roxanne's sister, Rori Sota, is expecting a baby Monday.

STANFORD'S FIRST IN VITRO BABY BORN

STANFORD—

The first baby conceived with the help of Stanford University Clinic's in vitro fertilization program was born to a Campbell couple.

The healthy 7-pound, 6.5-ounce girl, Jordyn Elizabeth Austin, was delivered naturally at Good Samaritan Hospital in San Jose at 4:13 p.m. on Aug. 27.

The mother, Karin Austin, is resting comfortably and recovering from the long-awaited event.

"Every baby is special, but this one is especially so," said her husband, Kevin. "We're really flying. We feel just great."

The Austins were referred to Stanford's in vitro fertilization program by their obstetrician, Dr. Carl Sgarlata, after unsuccessfully attempting for "a good solid two years" to achieve a pregnancy.

"There was no medical explanation for their inability to conceive," said Dr. Frank Polansky, the reproductive endocrinology and infertility specialist who directs the in vitro program. "They just needed a little help."

The Austins were among the first group of couples to go through the program, which began in October, 1985. Couples can undergo two types of treatment: in vitro fertilization (IVF), in which the eggs are fertilized by sperm in a petri dish and, after they develop into embryos, are implanted in the woman's uterus; and gamete intra fallopian transfer (GIFT), the method of choice for the Austins.

Like all women in the program, Karin began taking medication to enhance egg production two days after the start of her period. Six days later, physicians began examining her ovaries with ultrasound to check on the number and size of egg-bearing follicles. When the follicles were ready, Karin received an injection to trigger ovulation, the process in which the eggs are released from the ovaries to begin their travels through the fallopian tubes to the uterus.

About 36 hours later, Karin underwent a procedure called a laparoscopy to "harvest" the eggs. Meanwhile, Kevin produced semen, from which active sperm were placed in petri dishes with the eggs. Once the eggs were fertilized by the sperm in the petri dish, they were placed back in Karin's fallopian tubes, from where they naturally made their way into the uterus. Ten days later, Karin took a pregnancy test that turned out positive, and the rest, as the saying goes, was left up to Mother Nature.

If Karin had undergone IVF treatment, the fertilized eggs would have been kept in the petri dish until they developed into embryos of up to 16 cells, a process that takes two or three days. Physicians would then have placed the embryos directly into her uterus.

It may sound simple enough, but there's a lot that can go wrong with the process, said Dr. Emmet Lamb, chairman of Stanford's gynecology and obstetrics department. Only about 10 percent of the couples who start each cycle can expect to have a baby at the end of the process. But, he added, that compares favorably with the 2 percent monthly pregnancy rate that can be expected by the average infertile woman. And for some women who may have severely damaged fallopian tubes or none at all, IVF offers the only hope of pregnancy.

The program is not cheap, either. Couples are charged $5,000 per cycle of treatment, on a par with similar programs at Alta Bates Hospital in Berkeley and University of California, San Francisco. In spite of the cost, about 50 couples have gone through Stanford's program. While some women have begun treatment more than once for a total of 71 cycles started, only 43 have progressed far enough for eggs to be harvested, said Kathy Turner, nurse coordinator for the program. Three other couples are now awaiting births.

BEST BREAST CANCER PROGNOSIS IS FOR WOMEN AGED 45 TO 49

STANFORD—

Women who are diagnosed with breast cancer in their mid to late 40s survive slightly longer, on average, than young or elderly women diagnosed with the disease, conclude four Stanford University researchers in a letter published in the August 28 *New England Journal of Medicine*.

Their conclusions, based on a review of 20 years of medical literature and on an analysis of survival rates in a group of nearly 13,000 women with breast cancer, agree with the results of a major new Swedish study published in the same issue of the *Journal*, examining survival rates among 57,068 women with breast cancer.

"In all reports (that were examined) except one, the age groups that included patients 45 to 49 years old had the best prognosis," wrote Dr. Alice Whittemore, professor of family, community and preventive medicine at Stanford University School of Medicine, and her three colleagues, Janet Mohle-Boetani, a medical student; Stella Grosser, a master's degree statistics student; and Mary Malec, a research assistant.

When Whittemore and her colleagues calculated five-year survival rates in a group of 12,994 white women with breast cancer they found, again, that the overall five-year survival rate was highest among patients 45 to 49 years old and lowest among those younger than 35 years at the time of diagnosis.

"Since all the studies show the same result—that women 45 to 49 have a better prognosis—there must be some biological reason for it that we need to try to understand," Whittemore said in an interview.

One possibility that Whittemore favors but the Swedish group plays down is that the different survival rates in women of different age groups could relate to hormonal changes occurring around the time of menopause.

Such hormonal changes, particularly a decrease in estrogen levels, could slow breast tumor growth, Whittemore speculated.

Another factor that could contribute to lower survival rates in younger women is recent pregnancy, the researchers speculated, since hormonal changes during pregnancy are thought to worsen breast cancer.

However, Whittemore cautioned that these explanations are only guesses, and further research needs to be done before a full explanation can be proposed.

According to the Stanford study, the approximate five-year survival rates were 70 percent for women diagnosed with breast cancer when 35 or younger, 75 percent for women aged 35 to 44, 77 percent for those aged 45 to 49, and 73 percent for those 50 to 54 years of age.

SHUMWAY TALKS ABOUT HIS WORK IN PUBLIC LECTURE

STANFORD—

In a rare public appearance, heart transplant pioneer Dr. Norman Shumway will talk about his own three decades of transplantation research and prospects for the future in the field.

Shumway is featured speaker at the Stanford University Hospital's Friends of Nursing fall fundraiser, 6 p.m., Friday, Sept. 12 in Fairchild Auditorium at the Medical Center.

Shumway's talk is entitled "Heart and Heart-lung Transplantation: The Past, Present and Future." In 1968 he performed the first successful adult heart transplant in the United States. Since then Stanford has become one of the most active and successful centers with more than 408 heart and more than 35 combined heart-lung transplants.

Shumway in recent years has been an outspoken critic of the artificial heart, favoring instead both biologic transplants and implantable devices which assist the patient's own heart.

The lecture is to be followed by wine and a light buffet. Entertainment is to be provided by the Churchill Street Ragtime Jazz Band.

The public may make reservations by calling Mark James, Stanford University Hospital Nursing Administration, (415) 723-8545. Cost is $20 per person and seating is limited.

Friends of Nursing at Stanford is a nonprofit organization intended to promote professional excellence in nursing practice and to increase the public visibility of the nurse as a caregiver and teacher. The group sponsors fund raising and education events.

MONOCLONAL ANTIBODIES OFFER PROMISE IN ORGAN TRANSPLANT REJECTION

STANFORD—

Monoclonal antibodies may some day be used to track cardiac organ transplant rejection without the pain and complication of taking tissue from the heart, a Stanford University Medical Center immunologist says.

Dr. Randall Morris, a senior transplantation immunologist with Stanford's cardiac transplant program, says animal studies with rats indicate that the high tech "magic bullets" may offer an early diagnosis of rejection which can be detailed with photography instead of a surgical biopsy procedure.

Monoclonal antibodies, tailor-made protein molecules, have not realized their proponents' decade-old hopes of becoming a major cancer-fighting tool. But they are finding increasing potential use in the organ transplant and cardiac arenas. Scientists are starting to use monoclonals to diagnose heart attacks and treat kidney transplant rejection.

Morris presented the results of his monoclonal studies at the International Congress of the Transplantation Society in Helsinki, Finland, this month.

"We're encouraged even though there are still major obstacles which need to be overcome before this procedure could be considered for use on its own as a diagnostic test for human heart transplant rejection," Morris said in a recent interview.

"We've been looking for a long time for something which replaces the biopsy. That procedure is currently the only reliable test for organ rejection, but it's uncomfortable at best, and can be painful." It involves inserting a small scissors through a vein to snip off a small piece of heart tissue for analysis.

Morris described the experimental technique which has shown promise in rat studies:

The animal is injected with monoclonal antibodies, laboratory-refined protein molecules which have in effect been "programmed" to seek out and attach themselves in clusters to the damaged rejecting heart tissue. Minute quantities of radioactivity are attached to the monoclonals, and the radioactivity serves as a beacon to identify rejection.

The monoclonals, purified by a new technique developed by the researchers, are injected into the blood stream, where they travel until they come in contact with a protein called myosin, the substance responsible for making the heart contract, Morris explained. In healthy heart tissue, the myosin is covered with a membrane which deflects the monoclonals. But in hearts where rejection is occurring, the membrane is damaged and vulnerable to the cruising monoclonals.

The laboratory-engineered monoclonals, called antimyosin, are so specific that they recognize variations in myosin. In the animal tests, they bypassed myosin exposed in skeletal muscles. Instead, almost like a magnet, they attach only to the myosin in the heart, the scientist said.

The experiments involved sewing a second heart onto the abdomen of a rat. Since no drugs were administered, the second heart began rejecting within several days.

"The animals' own hearts serve as an effective control, because what we found was that the radioactive monoclonals attach themselves to the rejecting donor heart but bypass the non-transplanted healthy heart," said Morris. When the scientists looked at the rejecting heart tissue under the microscope, they could see the antibodies by using special stains.

more

"The next step is to photograph the radioactive monoclonals within the rejecting heart using X-ray style technology," Morris said.

Despite the encouraging results and the promise it offers to transplant patients, Morris indicates there are a number of serious barriers which need to be overcome before the monoclonal antibody test can be considered as a replacement for biopsies.

"We don't know if the test will be sensitive enough, at least initially, to pick up low levels of rejection that we can now find by biopsy, and secondly, we don't know how long it will take for the monoclonals to lodge in the right place. That's crucial because if it takes too long, we won't get results back fast enough to be effective. Third, there is a possibility that the the body will begin producing antibodies against the monoclonals, in effect causing the patient to build up an immunity against the test."

Still, the need to find a successful, safe and preferably comfortable test is vital, because rejection is perhaps the single greatest drawback to organ transplantation.

Rejection, caused by the immune system's natural tendency to fight off foreign tissue, is fought in patients with powerful drugs which are toxic if administered in high doses. The toxicity requires that physicians make a concerted effort to keep medication at the lowest possible level. But that caution renders at best a delicate balance which can easily be upset by rejection. Hence, the need for constant monitoring.

Morris believes that the current monoclonal test might be refined even further, perhaps eventually becoming a serum test requiring nothing more invasive than a simple blood drawing.

The immunologist and colleagues are currently testing to see if the myosin detaches from the heart and enters the bloodstream during rejection. If so, monoclonals used to test a blood sample from a patient might yield results as accurate as injecting the radioactive markers into the patient.

"Healthy people should have zero levels of the protein, persons who are rejecting may have higher levels of myosin in their blood," Morris explained. But initial tests of the laboratory test have not yielded definite results, he added.

Morris' colleagues were Patrick DeValeria, a Stanford medical student; Pi-Ju Cheng, a Stanford immunologist; William A. Clark, a biochemist at Michael Reese Hospital, Chicago; Brett Skogen and Johann Kim, research scientists at Tago, Inc., a Burlingame, Calif. biotechnology firm; and Frederic P. Pratt, of DuPont Biotechnology Systems, Wilmington, Del.

The work was funded by the National Institutes of Health, as well as the private Baxter, Hedco and McCormick foundations, and the Peyton Hawes Fund.

DELIVERY ROOMS OUTFITTED WITH BETTER EQUIPMENT THANKS TO NURSE'S OUTSIDE CONSULTING

STANFORD—

The way in which medicine and industry can cooperate for mutual benefit is illustrated perfectly by the work registered nurse Barbara Petree did for Stanford University Hospital and Hewlett-Packard Company.

Petree has been clinical nursing coordinator of Stanford's delivery rooms and at the same time has been a part-time consultant and community instructor for Hewlett-Packard.

In her dual role, she contributed to 10 years of research on the development of newer and better fetal monitors. That research ended with the introduction of the HP 80240A fetal ultrasound telemetry unit this month.

"By working with the equipment and giving HP our clinical feedback," she said, "we can participate in the process of technological development, which in turn helps us care for patients."

Since January, Petree has been working as a nurse educator with the Midcoastal California Perinatal Outreach Program administered by Stanford's Department of Gynecology and Obstetrics. She was working in the hospital, however, when nine of the original HP fetal monitors were purchased in 1974.

"At that time," she said, "we didn't have the money to adapt them for use in the delivery rooms, so HP fitted our four delivery rooms with a special connection box and extension arm to make the adaptation possible."

In gratitude for Petree's consulting and teaching activities within the company, HP last year donated two dual heart rate retrofit kits to the hospital to even further update later versions of a fetal monitor, two of which were purchased by the medical center's Auxiliary in 1983. The later version has a new ultrasound system which picks up the fetal heart rate in an external mode. "The delivery room budget has not allowed for the purchase of these kits for the past several years," Petree said.

The kits make possible the functions performed by the "newest generation" of dual heart rate fetal monitors, Petree said. "With pre-term deliveries, it's important to monitor both the baby and the mother because the maternal heart rate is increased by labor-suppressing drugs," she said.

With this latest monitor picking up the heart beats of one baby, twins, or mother and baby, nurses and doctors in the delivery room can obtain more medical information than ever before, said Petree.

Petree's involvement is an example of how a staff member serving the community can lead to direct benefits for the hospital, said Jeanne DeJoseph, perinatal assistant director of nursing.

"It is something I've done on my own time," said Petree, "in response to Stanford's encouragement of employees to get involved, and as an opportunity for my own professional growth."

In keeping with HP's tradition of using clinical people to teach community courses, Petree has instructed nurses, physicians, salespeople and biomedical engineers in the use of HP fetal monitors since 1975.

She also coordinated clinical trials in the hospital of HP's new telemetry unit, which uses ultrasound for transmission of signals. The prototype equipment makes it possible for a mother to be mobile while her baby is monitored during labor. "The sender she carries is about the size of a portable radio," Petree said.

Studies have shown that walking may shorten labor for some women, she said.

Another advantage of the new technology is that it is non-invasive, in contrast to telemetry units which require electrodes to be attached to the baby's scalp, she added.

Hewlett-Packard is selling the new units for $5,800.

CHRONIC SKIN DISORDER IDENTIFIED AS SELF-HEALING TYPE OF TUMOR

STANFORD—

A rare skin disorder that can afflict patients on and off for decades is probably a very slow-growing type of tumor, Stanford University Medical School doctors report in the August 21 *New England Journal of Medicine*.

By studying these rare self-healing tumors, scientists might be able to find new clues about the underlying causes of malignancy, said Dr. Jeffrey Sklar, assistant professor of pathology at Stanford and one of the investigators.

Sklar's colleagues on the study are Dr. Lawrence Weiss, assistant professor of pathology, Dr. Gary Wood, assistant professor of dermatology, Martha Trela, research assistant, and Dr. Roger Warnke, associate professor of pathology.

The disease, called lymphomatoid papulosis, is characterized by the intermittent appearance of small skin nodules which eventually break open, then heal, usually leaving small scars, the doctors explained. Many patients experience repeated episodes over a period of many years.

Despite its generally benign behavior, this disease has several features of a malignant cancer, Sklar said.

One hint which suggested the malignant nature of the disease is that occasionally patients develop an aggressive form of skin cancer called T-cell lymphoma, he said. Another is the observation that cells from the skin sores look malignant when observed in the microscope, he added.

But since common wisdom says that most cancers grow rapidly and inexorably, doctors had been unable to explain the decades-long course of the disease.

One possible explanation was that the disease, despite the malignant appearance of abnormal cells from the sores, is not really a tumor at all but an inflammatory reaction such as an allergy or infection.

To answer the question of whether this disease is truly a tumor or not, the Stanford scientists used biochemical methods to analyze genetic material from the abnormal cells. With these techniques they determined that the disease is most likely a lymphoma from the start, despite its indolent nature, Sklar said.

8-20-86 more

That finding in and of itself will not necessarily lead to improved treatments for patients who have the disease, he added, but it could provide new basic information about malignancy and how the body tries to control cancerous growths.

Sklar said that it's not known why this particular tumor grows so slowly and even appears to repeatedly heal itself. It could be that the body's immune system is able to hold the growth in check, he said. Another possibility is that there is something special about the particular cells that proliferate in this disease or about the abnormalities that make them grow.

Several years ago, Sklar and his colleagues began using a technique—based on recent advances in molecular genetics and immunology—for distinguishing cancerous growths from certain other types of cell proliferations. They used the same technique to determine that lymphomatoid papulosis is a tumor which is probably a very slow-growing, frequently self-healing, malignancy rather than an inflammatory process.

The technique relies on the fact that a cancer consists of a "clone" of genetically identical cells, all descended from a single cell that went awry. Inflammatory processes, which can outwardly resemble cancer, are not composed of genetically identical cells. Therefore, by analyzing certain genes within the genetic material, DNA, from cells in a tissue sample, scientists can determine whether or not it is a tumor.

In this study, the scientists removed skin samples from six patients with lymphomatoid papulosis and analyzed DNA from the cells. In five out of six patients, they found clones of cells, indicating that the disease is a tumor.

Sklar said that in the case of the sixth patient, the results were not definitive. In that case, there may have been too few tumor cells for detection in the specimen that was removed for study.

The research was funded by grants from the National Institutes of Health.

PHYSICAL THERAPIST HELPS SICK BODIES CATCH UP TO HEALTHY HEARTS

STANFORD—

Surgeons give transplant candidates a new heart, but Steve Sadowsky is among a group of Stanford University Hospital physical therapists which helps them to use it.

Sadowsky also helps patients rebuild chest muscles deteriorated from disuse after many months of having their breathing supported mechanically by a respirator.

His skills are based on 10 years of progressively greater responsibility, and he has the credentials and honors to prove it.

Sadowsky is one of about eight therapists in the nation to be certified by the national Board of Physical Therapy Specialties as a clinical specialist in cardiopulmonary physical therapy. His is one of six specialties in the past two years that the board has begun to recognize.

So what does he do for a patient with a new heart?

Before leaving the hospital, Sadowsky teaches the patient to be capable of riding a stationary bicycle for 25 to 35 minutes, climb two flights of stairs and walk a quarter of a mile.

Do all his patients meet these criteria?

"No, but many do, and some progress to significantly higher levels of performance. One patient eventually ran a marathon (26.2 miles), while another rode his bike several thousand miles across the country a few years ago. Of course quite a number are more recreationally active—they ride their bikes through Europe or whatever."

Sadowsky or one of his colleagues is one of the first staff people a transplant or other surgical intensive care patient is likely to meet during recovery.

"We're there usually on the first day after surgery and almost as soon as the transplant patient is extubated (breathing on his own). The first day the patient performs such things as bending the knee toward the face with the help of the therapist. On the second day patients are doing arm and trunk exercises while seated, and by the third day they're doing standing exercises beside their bed."

While individual therapy is useful for all patients, "it is especially critical for transplant patients who are taking powerful drugs (immunosuppressants) which can weaken their bones and can interfere with muscle function."

Transplant patients pose a special challenge to therapists because of their uneven physical condition.

"You have a healthy heart in a debilitated body. Even if the patient had lived an active life, they wouldn't have been able to exercise or be very active in the months before surgery.

"Our challenge is to bring the body up to the standard of the new, healthy heart and to assist in countering the side effects of the immunosuppressants."

The respirator patients pose a different sort of challenge.

These people are also desperately ill. Some of these patients have not been able to breathe for months without a mechanical respirator.

"When they begin to recover and start breathing on their own, they have the same problem faced by anyone who hasn't used a particular muscle for a while. But obviously it's much more critical to get someone's respiration muscles back to normal than, say, muscles in an arm or finger."

Sadowsky and his colleagues use a technique which involves stretching and applying resistance to the chest wall to reestablish regular breathing patterns and to stimulate the chest muscles that control breathing.

Whether patients have just had a transplant or are coming off the respirator, Sadowsky and his Stanford Hospital colleagues work under a physician's orders. But in the room or hospital gym, the therapist is often alone and must be ready to respond to an emergency.

"It's not superfluous that cardiopulmonary rescucitation (CPR) is required for all physical therapists," Sadowsky explained. He hasn't had to use it yet at Stanford, but when you're in a gym or alone at bedside with a recovering acutely ill patient, the skill is vital.

The Stanford therapy team works at the main hospital, Hoover Pavilion and the new Home Care facility in downtown Palo Alto. Several of Sadowsky's colleagues also work in the cardiopulmonary area and a few are actively working to achieve board certified specialization.

Besides Sadowsky's cardiopulmonary specialization, other specialties recently recognized by the Alexandria, Va.-based board include orthopaedic, pediatric, neurologic, clinical electrophysiologic and sports physical therapy.

Sadowsky needed four recommendations from physicians and physical therapists to qualify for consideration after meeting the basic criteria of five years of experience, a completed research project, six months experience each in teaching and experience in administration. Then to qualify Sadowsky sat through a 12-hour written examination last February in Anaheim.

He's proud of his board certification but he believes it benefits the patient as well.

"I would hope that the professional review process would give the patient reassurance that they're getting help from someone who has met specific criteria for handling and understanding their problem. The bottom line is we hope it makes the patient feel more confident and comfortable."

-more

3-3-3

Sadowsky became interested in physical therapy after he got out of the Marine Corps in the early 1970s. He had been injured and needed physical therapy himself.

"I observed the therapists, became interested in what they were doing and how much they helped me."

And his personal interests are consistent with his work with patients. When Sadowsky tells a patient to peddle his bicycle or climb stairs, he's doing nothing more than what he demands of himself.

He pedals his own bicycle 200 miles each week, commuting daily from Newark in the East Bay, commonly with a wide detour on the way home through the Santa Cruz Mountains. He has clocked respectable times in the Davis Double Century, a grueling 200-mile single-day bike event held annually in the Sacramento area.

Sadowsky, in an interview, pondered the definition of his profession and then stated:

"Physical therapy is both the art and science of helping patients who have myriad disabilities return to the highest level of physical and functional activities they are capable of." (No, he said, he hadn't written that definition down in advance).

Sadowsky has gone beyond the role of "hands on" care giver, however. He's been active in program development at Stanford.

Several years ago he participated in establishing the Department of Nursing's in-patient cardiac rehabilitation program, which starts physical rehabilitation for recent heart attack patients while they are still in the hospital. Sadowsky surveyed physicians to determine what was needed for the patients and then worked to develop a physical training program to facilitate those needs.

Sadowsky received his B.S. in physical therapy from the University of Illinois Medical Center School of Associated Medical Sciences in 1976. He came to Stanford in 1982, and in addition to his hospital duties, he taught basic skills to physical therapy students before the Division of Physical Therapy was disbanded last year.

In 1984, he received his master's degree from the University of Southern California. He is the author of several professional publications in his specialty and has regularly made presentations at scientific meetings in his field.

He also was invited to teach cardiopulmonary physical therapy at the University of Texas Medical Branch at Galveston as a guest lecturer in 1985.

HOW OCCUPATIONAL THERAPY DEPARTMENT GETS PEOPLE BACK TO WORK

STANFORD—

It took almost 18 months to get John Miller ready to return to work after an accident in which he lost several fingers, but learning to manipulate objects with his hands wasn't the most difficult part of his rehabilitation.

For Miller, the hardest part of readjustment was overcoming the excruciating pain of handling rough objects.

"He had some neuromas, sensitive nerve endings where he'd had a minor tumor that develops frequently in amputation," said Jennifer Green, occupational therapist in Stanford University Hospital's Physical and Occupational Therapy Department.

She explained that sometimes the neuromas are surgically removed, and sometimes people can be trained to "desensitize" themselves so they can tolerate the pain.

In the case of Miller (not his real name), the pain was so acute that all he was able to do at first was put his hand in water and squeeze a small sponge.

"Gradually he worked up to the point where he started doing clay projects, pushing things with his fingers," Green said. "Then he moved on to leathercraft projects where there was very light resistance, using a light hammer and tools, and then finally moved up to a wood-working project where he was actually hammering nails and tolerating what would be a work level of vibration to his hand."

That took a long time, but at the end Miller was ready to return to work at the same agricultural processing company that employed him before his accident.

His therapy illustrates some of the techniques used by the Stanford Physical and Occupational Therapy Department to get injured people back in the work force, but there are as many variations on those techniques as there are patients. The therapists stress individual attention and individual programs of rehabilitation.

A lot of the occupational therapy takes place in the outpatient unit at 457 Webster St., Palo Alto. The unit has almost every kind of tool needed to get patients ready to return to work, including a sophisticated piece of computerized machinery called a "work simulator" that can measure many levels of work-like exertion.

The central location of the outpatient services is important in work rehabilitation programs, Green said, because "one of the real issues in getting back to work is that you have to develop the ability to come to a work environment every single day. It's important that you're close to the program that you participate in because we're going to demand that you come five days a week, four hours a day."

Getting people back to work is the goal of the occupational therapy unit, but it's not always at the same job they had before they were injured. Sometimes they're not able to achieve the level of dexterity or endurance they had before and must try a different job.

more

An example is the 33-year-old registered nurse in the intensive care unit of a California hospital (not Stanford) who suffered a shoulder injury helping prevent an agitated patient from leaping out of bed.

"She worked on developing handling skills and proving her ability to lift. Her exact limitations had to be determined," Green said. "It's very hard to rehabilitate shoulders and there was no way she was going to be able to lift above her shoulders again—at least not the ICU monitors, which are like 30-pound boxes and you have to adjust them over your head and lift them around."

The woman will be able to remain in nursing, Green said, but not in intensive care. She'll probably become a nurse practitioner, "but she has to wait until her legal cases are cleared."

A lot of the people treated in the occupational therapy unit have legal cases pending and others are interested in pursuing legal possibilities.

"Some people come to us because they want to have somebody identify what their disability is," Green said. "We help them understand that, but we also help them understand what their abilities are.

"We really focus on what people are able to do and we try to help and encourage them to do as much as possible while they're here. And we try to reflect that ability to them because unfortunately most of the injured workers that we see have only heard the negative aspects of their problem—what they can't do."

The occupational therapy unit finds out exactly what they can do in a series of tests measuring strength, endurance and dexterity. Then they typically undergo retraining for four weeks and at the end of that time are reassessed.

At that point, the therapists can tell exactly how much progress has been made and make an evaluation of what progess can be expected in the future.

"We can tell people what they're going to get better at and what they aren't going to get better at," Green said, "and that information can go back to their vocational counselor or their physician to help them determine future goals for that person."

Reaching those goals sometimes means more than strengthening muscles and developing dexterity. Frequently, patients must learn new ways of doing work—new ways of lifting or positioning their bodies to cut down on physical demands and stresses.

For example, one 21-year-old man had undergone wrist surgery and was having trouble lifting things because of continuing pain in his wrists.

"The problem was he didn't know how to position his wrists to decrease pain and increase function," Green said. So therapists devised a set of splints that enabled him to hold his hands and wrists in a practical and comfortable position. Once he had developed better wrist positioning, he was gradually taken off the splints.

When patients have learned proper techniques and developed enough strength, they usually still have to go through what Green calls "work hardening." That means simply adjusting to repeated use of certain muscles for hours at a time. The work simulator is very valuable for that process, because it can be adjusted to produce almost any kind of muscle tension.

It's not just muscles that need "work hardening," Green notes. "There are work-related behaviors that are very important: attendance, punctuality, responding to supervision, problem solving, following directions. If people don't practice those, they lose them.

"One of the keys to this program is that early referral here following an acute injury will result in their work behavior continuing so that they never lose hope that they really can go back to work."

News Release

August 19, 1986

Fifteen years ago, Menlo Park resident Arden Farey was a busy industrial designer who thought about doing some cartooning but never really found the time.

But multiple sclerosis has gradually robbed him of his strength and the ability to use his limbs and now Farey has time for art.

"Now I do just what I want to," he said. "There's a certain freedom. I guess that's the positive side of being disabled."

Farey, who has retained his naturally upbeat personality despite his disability, creates his art by attaching felt tip pens and a special felt tip brush to a mouthstick. It is a technique he read about and then taught himself through trial and error. Using the mouthstick he has created political cartoons for the Times Tribune Newspaper, has done a series of illustrations for church brochures and drawn plans to improve his wheelchair.

One of his most recent projects was particularly satisfying for Farey; he entered a design in the Caregiver's Faire poster contest. The faire, to be held at the Menlo Park VA Medical Center, offers information and support for families who care for a disabled or elderly person. The winning poster would be used to publicize the faire.

Farey's poster was a starkly simple design with two cupped hands around a heart on a black background. In red letters were the words "Honor the caregivers who care and give again and again."

"It's almost a tribute to my wife," Farey said of the poster. "I had a deep, stirring feeling to say 'Thank you' with it."

-more-

His poster was selected from 12 entries; 1,500 copies of it will be reproduced and displayed around the community, and it will be sold on the day of the faire.

"It captures the essence of the faire, basically, which was to honor and support caregivers," said Nancy Delaney, VA social worker and faire committee chairperson. "This particular poster reached across all aspects of disability be it dementia, quadriplegia, frail elderly. That was a very, very difficult idea to portray artistically."

Farey came up with eight to 10 ideas before deciding on his final version. Some of his early ideas included portraits of a caregiver helping a disabled person, but he decided that was too specific. Once he decided on the symbol, it took about eight hours to produce, he said.

The poster contest came to Farey's attention while he was a patient in the VA's Respite program. At the Respite program, disabled or elderly veterans spend one week four times a year as a inpatient to give their caregiver some rest. Farey has been part of the program for over a year. He said it allows his wife to take a vacation and sleep through the night without waking, as he must be rolled over in bed every three hours.

Farey can be reached at 854-1733. For more information about the Caregivers Faire call 493-5000 ext. 2458.

STANFORD HOSPITAL ANNOUNCES RATE INCREASES

STANFORD—

Stanford University Hospital's rates for rooms and services will be increased Sept. 1 by an average of 6.7 percent—the smallest rise in 13 years—Sheldon King, president and chief executive officer, announced Monday (Aug. 18).

The small increase reflects the determination to keep patient costs as low as possible, King said.

The new rates were approved by the Board of Hospital Directors Aug. 13. At the same time, the directors approved an operating budget for the 1986-87 fiscal year of $191.4 million, 2.4 percent lower than the $196 million budget approved for 1985-86.

That lower budget was accomplished despite an increase in inflation and depreciation costs of $13.4 million and is principally the result of the hospital's downsizing effort this year. The downsizing, which included staff reductions, made it possible to hold the budget total down without diminishing Stanford's ability to offer the highest quality medical care, King said.

University trustees, as general members of the Hospital corporation, must approve the budget for the next fiscal year. Their approval is not required for the rate increases.

The 6.7 percent price increase exactly matches the percentage increase forecast in the inflation facing the hospital. One factor pushing costs up during the coming fiscal year is a 69 percent increase in the cost of general liability and malpractice insurance.

Although the increases will average 6.7 percent, some areas will have higher increases, some lower. Patients requiring higher levels of care, such as those in intensive care units, will have higher increases. Those requiring less care will have lower increases.

For general care patients, the increase averages only 4.2 percent. In some specific areas, prices will remain the same or actually decrease.

Some examples of the new rates:

- A semi-private room in the medical/surgical unit with Level 1 care (up to five hours of nursing care daily) will be $414. If 24-hour housestaff coverage is provided, the rate will be $442.
- A semi-private room for obstetrics patients, also with Level 1 care, will be $387 without housestaff coverage and $415 with such coverage.
- All beds in the Alcohol and Drug Treatment Center will be $417.

STANFORD SPONSORS ONE-DAY WEIGHT LOSS COURSE

STANFORD—

A one-day workshop intended to help people lose weight and keep it off has been scheduled Saturday, Aug. 23 by the Stanford University Hospital Department of Dietetics.

The program is open to the public. It will run from 8:30 a.m. to 2:30 p.m. in Fairchild Auditorium at the south end of the Medical Center, said Diane Madgic, clinical dietitian.

Entitled "Basics for Safe and Successful Weight Management," the course is described as a "skillpower workshop" and is intended to help people bypass the "yo-yo syndrome," a cycle of weight loss followed by weight gain.

The workshop, Madgic said, includes sessions teaching "the skills to combine dietary moderation, behavior modification, exercise and frame of mind conducive to maximizing one's health and fitness."

Advance registration at $35 is advised and includes the workshop and brunch. On site registration is $40. For further information, contact dietitian Jane Dunn, Department of Dietetics, (415) 723-6904.

WILLIAMS APPOINTED ACTING HEAD OF NEW CHILDREN'S HOSPITAL AT STANFORD

STANFORD—

John R. Williams, executive director of Children's Hospital at Stanford, has been named acting director of a new consolidated children's medical center on the Stanford campus.

The new Children's Hospital at Stanford, scheduled for completion in 1989, will adjoin Stanford University Hospital and will house the full range of programs currently offered by Stanford's Pediatrics Department and Children's Hospital. Construction of the new facility will be funded partially by a $70 million gift to the University from Lucile and David Packard.

Williams will design administrative systems for the New Children's Hospital at Stanford and plan the transition from the existing operation. He will report to the board of the new hospital, which is a joint venture between Stanford University and the current Children's Hospital.

Williams earned a Master of Public Health degree in hospital administration from UC-Berkeley in 1964 and joined Children's Hospital at Stanford in 1973. He was appointed executive director of Children's Hospital in 1979.

Previously, he held administrative positions with Peninsula Hospital in Burlingame and Community Hospital of the Monterey Peninsula.

A fellow of the American College of Hospital Administrators, Williams is an active participant in professional and industry associations. He has served as president of the California Association of Children's Hospitals and as a delegate to the American Hospital Association.

MEDICAL SCHOOL TO DEDICATE NEW MAGNETIC RESONANCE RESEARCH LAB IN MEMORY OF NOBEL LAUREATE FELIX BLOCH

STANFORD—

A new state-of-the-art laboratory for research in magnetic resonance imaging will be dedicated at Stanford University Medical Center Friday, October 3 in honor of the late Felix Bloch, Stanford University's first Nobel laureate.

Bloch, who was a physics professor at Stanford from 1934 until his death in 1983, shared the Nobel Prize in 1952 with Edward Purcell for inventing the fundamental method used in the magnetic resonance imaging (MRI) process.

MRI is thought to be one of the most important advances in diagnostic medical imaging since the X-ray was introduced.

The laboratory, to be known as the Felix Bloch Laboratory for Research in Magnetic Resonance Imaging, was constructed as a result of a gift from Rhoda and Elliott Levinthal.

Housed in the Medical School's Department of Diagnostic Radiology and Nuclear Medicine, the new lab provides a much-needed MRI facility within the Medical School that can be devoted exclusively to MRI research, according to department chairman Dr. Ronald Castellino.

"We are particularly delighted that the laboratory will honor professor Bloch in view of his enormous contributions to this technology," Castellino added.

The lab is equipped with a Resonex MRI scanner, an innovative new machine with great flexibility for imaging research, said Dr. Leslie Zatz, professor of radiology who has been appointed the new laboratory's director by Castellino.

"Stanford was fortunate in having one of the two inventors of magnetic resonance on its faculty," Zatz said. "It is very appropriate to remember professor Bloch by having this laboratory apply his technique to improving patient care in medicine."

Levinthal, who received his doctoral degree with Bloch in the 1950s and is now director of the Stanford Institute for Manufacturing and Automation, noted that "Felix was especially pleased to find his ideas had broad utility, and he was thrilled that his basic work would find such rich application to a field that would relieve human suffering."

Bloch, who was born in Zurich in 1905 and obtained his physics doctorate with Werner Heisenberg, made numerous other fundamental contributions to physics, including his thesis research which applied quantum mechanics for the first time to the conductivity of metals, an achievement that underlies the modern science of materials.

MRI is based on the nuclear magnetic resonance (NMR) phenomenon discovered independently by Bloch and Purcell. Subsequent to these pioneering experiments, Bloch and his students further developed the field, achieving a revolutionary impact on chemistry and biology with their discovery of the "chemical shift," which has made possible the nondestructive analysis of chemical and biochemical materials.

Bloch participated for many years as a consultant in the development of the first commercial NMR instrumentation, and according to Levinthal, just prior to his death Bloch had become involved in the emerging development of clinical MRI machines.

more

In MRI, the patient is placed in a powerful magnetic field that is capable of rapidly aligning the nuclei of atoms in the body that possess a property known as spin. Each water molecule has such proton atoms. Radio waves beamed at the patient "tilt" the nuclei, which then emit signals that can be used to form images of internal body structures.

"The potentials of MRI have only been scratched so far," Zatz said. It promises to provide highly detailed medical information in areas as diverse as psychiatry, oncology, neonatology and cardiology, and since it involves no radiation it is less risky than X-rays, he said.

The new laboratory will serve as a clinical research facility to explore new applications of MRI in medicine. The MR imaging technique can also be a useful new tool for other areas of research, Zatz noted.

The facility is already up and running, he added. The first Felix Bloch fellow, Dr. Adam Ratner, was appointed on July 1, and scanning of volunteer subjects began in August.

Zatz listed a few promising areas of research:

- Techniques to improve spine scanning, which could replace myelography in diagnosing spine diseases such as herniated disc or tumors;
- Development of MRI for diagnosing liver tumors, and distinguishing benign from malignant growths;
- Exploring MRI's ability to replace angiography in diagnosis of congenital heart lesions;
- Use of MRI to detect tissue rejection in its early stages in heart transplant patients, eliminating the need for more invasive heart biopsies;
- Use of MRI to scan for abnormal brain development in premature infants.

"Stanford University provides a particularly rich environment for magnetic resonance research," Levinthal noted. Among the other laboratories on campus are the Magnetic Resonance Systems Research Laboratory, directed by Albert Macovski, professor of electrical engineering and diagnostic radiology; a Chemistry department-based program directed by professor Harden McConnell; the Stanford Magnetic Resonance Laboratory directed by pharmacology professor Oleg Jardetzky; and an MRI clinical and research unit located in Mountain View, directed by Dr. Dieter Enzmann, associate professor in the Department of Diagnostic Radiology and Nuclear Medicine, who also oversees the department's entire MRI program.

In addition, the School of Medicine has just received from the University Trustees concept approval for a magnetic resonance spectroscopy research center to investigate non-imaging applications of MR in medicine and basic research.

The Bloch lab will act as a "beta" test site for Resonex instrumentation, Zatz said, which means that new features on the MRI machine will be evaluated here.

One of the specific advantages of the Resonex machine is that unlike most MRI devices, it can operate in a small space, Zatz said. The expensive external shielding required for most machines, which use superconducting magnets, is not needed for the Resonex device, which is built around a large iron magnet which confines the magnetism to a small area. This feature makes it possible to work close to the unit. "This may be helpful in studies of small infants or very sick individuals who need to be monitored," Zatz said.

The dedication ceremony will include a brief symposium on the status of magnetic resonance research at Stanford, followed by a formal dedication at which Levinthal, Castellino, Zatz, Enzmann, Medical School Dean David Korn, and Stanford University President Donald Kennedy will give talks. Tours of the laboratory and a reception will follow.

Attendance at the event is limited to invited guests only.

STANFORD NURSES GIVE TIPS TO WORKING NIGHTS

STANFORD—

If working the night shift leaves you feeling a bit wrung out, some tips from a couple of Stanford University Hospital nurses may be just the thing to get you functioning at your best during the day as well as the night.

Disturbed sleep, disrupted eating patterns, lack of exercise and unbalanced work schedules were the major problems identified by night nurses in a study by Marjorie Keys and Genevieve Fiedor, night nursing supervisors at Hoover Pavilion.

Tips on how to resolve these problems and more are included in their new pamphlet, "Welcome to the Night Shift." Some more apparent solutions include eliminating or covering up "day noise," exercising regularly and eating well. The researchers also suggest that nurses and other night workers develop positive attitudes about their work shifts, schedule family meals and other activities around their work schedules, plan for days off to coincide with family members and balance work with social events.

The pamphlet is the result of the supervisors' research project for which they questioned about 339 night nurses. About 79 percent of the 429 nurses initially contacted to participate responded.

All nurses, the researchers said, are required at some point in their career to work the night shift. They are often faced with patient care crises and need to be able to think clearly.

"We noted that some nurses felt that sleeping during the day is impossible," they said. "In addition, we've seen nurses who work the night shift come to work feeling tired. Many of these problems stem from lack of sleep. This sleep is of poor quality and insufficient duration."

The researchers found that the longer nurses have worked nights permanently, the better their coping mechanisms are. In addition, their work has less of a negative impact on their lives.

WEIGHT LOSS VOLUNTEERS SOUGHT FOR DIET-EXERCISE PROJECT

STANFORD—

A Stanford program will be comparing whether men and women have been created equally—or at least lose weight equally, and if they do, what's the best way.

The Stanford Center for Research in Disease Prevention (SCRDP)is looking for 270 moderately overweight persons—half of them men, half women—to help learn if diet alone, or a combination of diet and exercise work most effectively to shed excess pounds and improve the chance of avoiding heart disease.

A previous study, released in March, showed that either moderate dieting or increased exercise were equally effective at taking off pounds and concurrently improving such general health markers as blood cholesterol and blood pressure levels.

The new project, starting Oct. 23, will be studying for the first time at Stanford whether men and women respond equally to the same approaches, most particularly the double-barrelled diet and exercise approach. Volunteers will be followed for at least two years to see what combination of diet and exercise is best for long-term improvement.

Dr. Peter Wood, associate director of SCRDP and principal investigator of the study, said only men were used in previous trials, because the investigators felt having a single sex would make the results easier to analyze and because men are at higher risk for heart disease.

"But when we recruited volunteers we kept getting calls from women who said, 'why can't we participate?' So we decided to design a study where we could involve both sexes," Wood explained. The National Institutes for Health, which funded the study, agreed that a comparison of the sexes was appropriate and timely, he added.

Wood said he doesn't expect difficulty in finding enough women. "Generally, women outnumber men in seeking weight control programs by about 10 to one. Our challenge will be in keeping an even balance for scientific reasons."

The participants will be divided randomly into one of six groups—three for men and three for women.

One set of males and females will be coached on a heart healthy, calorie-reduced diet and asked to remain sedentary.

A second set will receive identical dietary instruction and will also participate in three-times-per-week supervised exercise. Wood said this will consist for the first six weeks of coed indoor fitness classes, and then primarily of outdoor walking and jogging sessions.

And finally, a delayed weight loss group will be asked to make no changes in diet or exercise for one year, so that the researchers can compare the changes in the other groups to the control group. This group will be given a weight loss program later at the end of one year.

All of the participants will receive periodic physical exams, including monitoring of cholesterol and blood pressure, as well as a precise measurement of their body fat and cardiovascular fitness, Wood said.

Volunteers should be moderately overweight, aged 25-49, and nonsmokers. Alcohol consumption must be less than four drinks per day. Women must be premenopausal and not planning to become pregnant for the next two years.

Appropriate weight ranges for volunteers are based on a participant's ability to lose substantial weight so that changes in health risk can be seen clearly. For example a 5-foot-10 male would need to weigh between 181 and 230 pounds, while a 5-foot-4 female should weigh 145 to 186.

There is no charge to participants, Wood said.

Other principal researchers include co-investigator William L. Haskell, Ph.D., who like Wood is an associate director of SCRDP. The project director is Marcia Stefanick, Ph.D., a research associate at the center.

For further information or to volunteer, call (415) 725-5013 between 2 and 5 p.m. on weekdays. Orientation sessions for prospective volunteers will start Oct. 23 and continue for several months.

FORMER OPERA OFFICIAL APPOINTED TO MEDICAL FUND-RAISING JOB

STANFORD—

Susan Overman, most recently director of development for the San Francisco Opera, has been appointed to manage the Stanford University School of Medicine fund-raising programs, David L. Mitchell, director of medical development, announced.

Mitchell said in a Sept. 22 announcement that Overman will report to him as associate director of medical development. She holds the additional title of director of development for the medical school.

Her specific duties will involve supervising selected development activities for the School of Medicine, with an emphasis on the school's ongoing support programs, Mitchell said. She will also concentrate on completing that portion of the Medical Center Agenda Campaign that involves fund raising to increase the school's endowment.

Overman is the Medical School's counterpart to the department's other associate director, Paul Edwards, who heads development for Stanford University Hospital.

Since 1984, Overman served in the top fund-raising capacity for the opera. For five years previous to that, she was director of resource development for the CARE Foundation in New York, where she directed a 78-person fund-raising staff for the nonprofit charitable organization, Mitchell said.

She earlier served as deputy director of development for the Save the Children Federation in Westport, Conn. Currently, she serves as a trustee of Earlham College, the Pennsylvania institution where she received her B.A.

She has a master's degree in English from Indiana University, and has taught literature and journalism in secondary schools.

"It will be exciting to work with Susan Overman, who brings a rich breadth of experience to this crucial fund-raising position," Mitchell said.

LEADERS AT STANFORD OPPOSE PROP. 64

STANFORD—

Acting as individuals, eight Stanford faculty members—including President Donald Kennedy and Medical School Dean Dr. David Korn—have signed a public statement calling for the public to defeat Proposition 64, the AIDS initiative.

A total of 12 prominent Bay Area leaders signed the anti-Proposition 64 statement, which appeared as a paid political announcement in the Sept. 24 editions of the independent community newspaper, the *Palo Alto Weekly*. The ad was sponsored by Scientists & Citizens Against 64, which is headed by former SRI International scientist Felix Smith.

In an interview, Korn, chairman of the National Cancer Advisory Board, said, "As an individual who serves in a position of public responsibility, I am very cautious about making statements involving political issues.

"But this measure is not a matter of weighing the normal subtleties of public policy. It has been presented to the public based on patently inaccurate scientific information which unproductively feeds on public fears of a genuine health threat."

The paid advertisement seeks contributions to support a public education campaign to provide scientific information for the public before the November election.

The statement augmented the widely reported arguments of Proposition 64's opponents that AIDS is not easily communicable and to treat it as such in the public health codes would foster administrative confusion, ply needlessly and irrationally on the public's fear of the problem, and hamper efforts to eradicate the disease.

The initiative, backed by supporters of political activist Lyndon LaRouche, would extend to AIDS state public health code requirements now used for certain highly communicable diseases.

Although the degree of enforcement would be subject to interpretation by health officers and ultimately the courts, opponents believe the measure would lead to diverting funds away from AIDS control activities to administrative and/or legal costs of administering the health code.

Opponents have said that Proposition 64 could increase the spread of AIDS, because high risk individuals would be unlikely to seek screening or medical care because of fear of being quarantined or fired when their risk or disease status was publicly disclosed.

9-29-86

more

Proposition 64 "is opposed by the virtually unanimous opinion of the medical, scientific and public health communities of California. They are convinced that it is based on false science, and that its passage would make it more difficult to fight the AIDS epidemic in California," read the newspaper statement.

Additional Stanford faculty signatories included 1980 Nobel Prize winning biochemist Dr. Paul Berg; chemistry professor Dr. Carl Djerassi; emeritus engineering faculty member Edward Ginzton, co-founder of Varian Associates; Dr. R. Hewlett Lee, Palo Alto Medical Clinic executive director and clinical professor of surgery; W.K.H. Panofsky, former director of the Stanford Linear Accelerator Center; and Law School professor and state assemblyman Byron Sher.

Other signatories included real estate developer Ryland Kelley; Sunset Magazine publisher Melvin Lane; former Palo Alto Mayor Betsy Bechtel; and businessman Edwin A. Seipp. Neither occupations nor affiliations were listed in the ad.

Major groups which have publicly opposed the initiative include the American Red Cross, the California Medical Association, the California Hospital Association, the California Nurses Association, and the California Dental Association.

"The bottom line involving this initiative is that everyone wants to see a rapid culmination of the AIDS epidemic, but Proposition 64 would make that significantly more difficult. Because the measure is based on scientific inaccuracies, it will send the fight against AIDS off in unproductive directions, diverting resources and attention away from the most productive tracks of research and public policy," Korn said.

Proposition 64 gained widespread attention several months ago when a state court took the unusual step of ordering several "false and misleading" statements removed from the official ballot arguments mailed by the state to registered voters.

The statements indicated that AIDS (Acquired Immune Deficiency Syndrome) could be spread by casual contact.

"The facts are AIDS has never been 'caught' except by the most intimate contact, i.e. by sexual intercourse, by direct injection of blood (by transfusion or in intravenous drug use), or by passage from an infected mother to an infant in childbirth," the newspaper statement said.

In a speech Sept. 4 in San Francisco, state Department of Health Services Director Dr. Kenneth W. Kizer said that Proposition 64 "would hurt our efforts to control the spread of AIDS by fostering distrust and disrupting implementation of our public health programs, and by diverting resources away from AIDS control activities."

ADVANCE FOR RELEASE FRIDAY, SEPTEMBER 26, 1986

HUNTINGTON'S DISEASE ADVANCE REPORTED BY STANFORD SCIENTISTS

STANFORD—

Stanford University Medical School scientists have identified a protein on brain cells that may be involved in the development of Huntington's disease, they reported in the October 3 issue of the journal *Science*.

The finding opens up new avenues of research toward finding a drug that may be able to slow or halt Huntington's disease, a rare but significant hereditary condition thought to affect approximately one in 20,000 individuals, said Dr. Dennis Choi, Stanford assistant professor of neurology who led the study.

The protein is a receptor molecule found on the surface of certain brain cells, including those known to degenerate in Huntington's disease patients. Although the receptor protein itself is probably not the culprit that causes the disease, the scientists believe that it may be the docking point for chemicals that ultimately cause the cell destruction.

Choi, who carried out the research with Jae-Young Koh, a graduate student, and Dr. Stephen Peter, a postdoctoral fellow, was cautious about the therapeutic implications of the discovery and stressed that the research did not represent a breakthrough or a new treatment for Huntington's disease.

"We know there are drugs that can specifically block these damaging chemicals from docking, but we're quite a way from tests in humans," he said.

The major significance of the finding, he suggested, is that it confirms previous theories while moving researchers a step closer toward understanding at the molecular level what causes the brain cell death seen in Huntington's disease.

But the finding is certain to be of broad interest because Huntington's disease is representative of a group of degenerative brain diseases such as Alzheimer's disease, Parkinson's disease and others, which as a class constitute the fourth leading cause of death in the United States, according to Choi.

The finding could provide new clues about the molecular mechanisms underlying the development of these conditions as well, he suggested. "It's a class-action kind of thing. If we can start to get an idea of what causes one of these diseases, it may spill over into the others."

The research was carried out with support from the National Institutes of Health, the Wills and Hereditary Disease Foundation and the John A. Hartford Foundation.

Huntington's disease is transmitted in what geneticists refer to as an autosomal dominant mode. This means that, on average, half the children of an affected parent will acquire the condition. However, the disease usually only appears between the ages of 30 and 50.

Involuntary and jerky movements, as well as deterioration of mental function are typical symptoms, which are thought to arise primarily as a result of degeneration in two areas of the brain, the striatum and the cortex. The striatum helps control movements and the cortex is involved in higher mental functions such as language and conscious thought.

Choi said that the Stanford work is based on a flurry of recent advances in Huntington's disease research.

At one time, he explained, scientists believed that brain cells in the striatum died in a widespread fashion in Huntington's disease patients. However, recent studies by scientists at Massachusetts General Hospital (MGH) have shown that only certain brain cells degenerate while others are completely spared. "The pattern of cell death is a 'fingerprint' that is characteristic of Huntington's disease," he explained.

The MGH scientists found that by injecting into animals certain chemicals, which had been suspected of playing a role in causing Huntington's disease, they could reproduce the disease's "fingerprint" in the animals' brains.

Rather than using live animals, Choi and his colleagues studied the chemicals' effects on brain cells grown in dishes in the laboratory. Confirming the MGH findings, they observed that a chemical called quinolinic acid, which is normally present in the brain in small quantities, reproduced the Huntington's disease fingerprint: it killed the brain cells that degenerate in Huntington's disease patients but spared the cells that survive in patients with the disease.

Several other chemicals related to quinolinic acid, however, did not reproduce the Huntington's disease fingerprint.

"These results support the hypothesis that the disease may be caused by excess exposure to quinolinic acid or some highly similar substance," Choi said.

But Choi and his colleagues were able to go one step further. Their study suggests that some cells die and some cells survive quinolinic acid exposure because of the different types of receptor proteins that dot their surfaces. The dying cells possess a receptor protein that quinolinic acid "docks" onto. The cells that are spared may lack this receptor, Choi said.

"If this receptor is in fact critically involved in the progression of Huntington's disease" Choi said, "it is possible that blocking the receptor may prove to be therapeutically useful. We already know of some drugs that block this receptor, although much work remains before tests on patients could be done."

STANFORD HOSPITAL TO SPONSOR MEDICAL PROGRAMS ON KQED

STANFORD—

"Health Matters," a 22-week television series sponsored by Stanford University Hospital, will begin Oct. 4 on KQED (Channel 9) and its sister station, KQEC (Channel 32).

The series will feature prominent physicians or other health authorities discussing a wide variety of medical problems, including such topics as arthritis, colorectal cancer, heart disease and drug/alcohol rehabilitation.

Each program includes a 15-minute feature story on a specific medical problem, sometimes involving advances in research and sometimes showing individuals trying to cope with the problem. The second half of the program has a moderator interviewing physicians or other medical authorities who are knowledgeable about the problem in question.

The feature portion of the opening program, "The Assisted Heart," was filmed at Stanford because the School of Medicine has participated in research and development work on heart-assist devices, in particular the left ventricular assist device (LVAD).

Medstar, a Pennsylvania-based television company, is the producer of "Health Matters." This season, the program is being shown in 30 television markets across the nation.

The shows will be hosted by Carol Kline, a former news anchor at an ABC affiliate in North Carolina and producer and host of two shows in Japan. She also taught broadcast writing and television production at two universities in North Carolina.

Taking to the airwaves is not new for the hospital. Its clinical "firsts" generated by faculty research are featured regularly on local and network television.

But this is the first time the hospital has underwritten a weekly television series to bring up-to-date health information regularly to the general public.

"University hospitals have services and expertise as well as nationally recognized physicians and programs unique to the communities in which they reside," said Spyros Andreopoulos, director of Stanford Medical Center communications and consultant to the show. "They are, therefore, well-suited for taking leadership in this area."

The goal, he added, is to have a program that is credible, informative and in keeping with Stanford's overall philosophy of presenting topics from differing points of view.

more

9-24-86

The producer of "Health Matters" retains complete editorial control of each program. In addition, the guests picked by the producer for their particular expertise include full-time faculty, area physicians and other health professionals.

Among the medical experts scheduled to appear on segments of "Health Matters" are Dr. Michael Eliastam, director of emergency services at Stanford Hospital; Dr. William Hazle, medical director of the Stanford Alcohol and Drug Treatment Center; Cecele Quaintance, director of the Mid-Coastal Perinatal Outreach Program; Dr. Norman E. Shumway, chairman of the department of cardiovascular surgery at Stanford; and Dr. Hewlett Lee, executive director of the Palo Alto Medical Clinic.

All of the programs will be shown at noon on Saturdays and repeated at 7 a.m. on Fridays. They will also be repeated at 9 p.m. on Thursdays on KQEC.

The complete list of programs and their initial showing dates:

BETTER STRATEGY NEEDED FOR CHOOSING DELIVERY METHOD IN PREGNANT WOMEN WITH HERPES

STANFORD—

The standard procedure for determining whether a pregnant woman with herpes needs a Caesarean section is unreliable, according to a new Stanford University Medical School study published in the September 25 *New England Journal of Medicine*.

The reason for performing a C-section on a woman with a history of genital herpes is to protect her baby from possible exposure to the herpes virus as the infant passes through the birth canal, said Dr. Ann Arvin, associate professor of pediatrics at Stanford and study leader.

Newborns who get the disease at birth are at risk of developing serious illness which can spread to the liver, lungs and brain, she explained.

Only a fraction of women—approximately one in 2,000—who have a history of genital herpes are likely to pass the infection to their babies during a vaginal birth, the doctors said.

Among the women with a history of herpes who have no active disease as delivery approaches, it is difficult to determine who should have the surgery.

Up to now, doctors have relied on a series of weekly lab tests to detect the herpes virus in the vagina during the last weeks of pregnancy. A positive test in an asymptomatic woman suggested that she should undergo a Caesarean delivery to protect her child.

But what the Stanford study has now shown is that the test is so inaccurate in predicting which infants will be exposed and come down with the disease that it is essentially useless in determining which herpes carriers should undergo a C-section, explained Dr. Paul Hensleigh, a co-author and associate professor of gynecology and obstetrics.

The unreliability of the test is due to the fact that it takes two to four days to get results, but the virus may be present in the vagina only for brief episodes, Hensleigh explained. "The test itself is an accurate one," he added, "but because of the time delay in getting results, the information is no longer applicable."

Other co-investigators on the study include Dr. Charles Prober, associate professor of pediatrics; Deborah Au, research nurse; Linda Yasukawa, research technician; Drs. Alec Wittek, Paul Palumbo and Sharon Paryani, postdoctoral fellows; and Dr. Anne Yeager, who had been an associate professor of pediatrics prior to her death in 1984.

Obviously a better strategy is badly needed, Hensleigh said, but none is yet available. "In the meantime, what we're recommending to doctors is that C-sections be performed in women with a history of herpes only if they have active lesions at the time of labor," Hensleigh said.

Approximately 35 to 40 percent of women with a history of herpes deliver by Caesarean section, Hensleigh said, as compared to the rate of Caesarean delivery in women without herpes, which is about 20 to 25 percent. Much of this increased C-section incidence has been due to the use of the weekly cultures, he added.

In the past, recurrent herpes infection was thought to affect about three to four percent of women, based on reports from women themselves. But newer information, based on blood tests, suggests that as many 20 percent, or one in five women, may be carriers of the disease and at risk of passing it to their newborn child, he added.

LOW-FAT, HIGH-CARB DIET MAY POSE HEALTH RISKS FOR SOME AND NO BENEFIT FOR MOST, STANFORD RESEARCHER SAYS

STANFORD—

Low-fat, high-carbohydrate diets — currently recommended to decrease the risk of developing heart disease — actually may pose health risks for some people, a Stanford Medical School professor of medicine said.

Physicians at a consensus conference last year sponsored by the National Institutes of Health concluded that "all Americans" (except children under 2 years of age) should reduce their fat intake from 40 to 30 percent of all calories consumed, including reductions in saturated fats and cholesterol — the culprits of heart disease.

But, in an article in the July issue of the *Journal of Nutrition*, Dr. Gerald Reaven, a noted expert in diabetes, criticized the recommendation to "all Americans" as being too broad. "There was nobody invited (to the conference) who held a contrary view," he noted.

A low-fat, high-carbohydrate diet may increase the risk of developing heart disease in people with impaired tolerance to glucose (sugar), Reaven said. Thus, diabetics and people who are obese and inactive "could possibly lose more than they would gain by adopting the recommendation," he said.

The recommended diet is also "potentially dangerous for people who have hypertension," he added.

Although the recommended diet probably won't make any difference for most people," diabetics and people with high blood pressure make up a "substantial proportion" of the American population, Reaven noted.

The diet should be recommended only for "people who have a high plasma LDL-cholesterol concentration," he said. More research is needed before such large-scale recommendations can be made, he indicated.

"If all Americans were young, slim, and physically active, the impact of the proposed dietary change would be minimized," he said. But, "given our aging, overnourished, and relatively sedentary population," all Americans should not adopt the proposed diet.

In people with impaired glucose tolerance, the increase in carbohydrates needed to offset the decrease in fats is likely to cause glucose and insulin levels to increase above normal, Reaven said.

Studies in diabetics and non-diabetics who have abnormally high insulin and glucose levels show that such increases enhance a person's risk of developing heart disease. In fact, the frequency of heart disease in diabetics is two to three times that of the population at large, Reaven said.

The consensus conference based its recommendation on evidence indicating that people who consume more saturated fat have greater levels of LDL-cholesterol in their blood. Studies implicate this fat and "bad" form of cholesterol as causative agents of heart disease, Reaven said.

The proposed dietary change assumes that reducing the intake of fats decreases LDL-cholesterol levels in blood, but "there is no evidence that this can actually be accomplished in a free-living society," Reaven said. Thus, the proposed diet "may help nobody."

Furthermore, "there is substantial evidence" that low-fat, high-carbohydrate diets are likely to decrease HDL-cholesterol (good cholesterol) more than LDL-cholesterol (bad cholesterol), which the diet is targeted to reduce, Reaven said. And, "If your HDL goes down more than your LDL goes down you may have made your risk (for heart disease) worse," he said.

The proposed dietary change also would increase levels of VLDL-triglyceride (a fat) in blood, which studies indicate may increase a person's risk of developing heart disease, Reaven said. But most physicians ignore the effects of VLDL-triglyceride as transient and not of primary concern, he said.

However, they cite a 25-year-old study on South African prisoners, which cannot be extrapolated to "all Americans," Reaven said. And some researchers do identify VLDL-triglyceride as a primary risk factor. It is definitely a primary risk factor for diabetics, he said.

STANFORD / SUNNYVALE STUDY SEEKS TO DETERMINE OPTIMUM EXERCISE RATE

STANFORD—

Most health authorities agree exercise is beneficial, but there is still disagreement on how vigorous that exercise needs to be, particularly for people who are middle-aged and who have been sedentary for some time.

Researchers from the Stanford University School of Medicine hope to find a key to the optimum amount of exercise in a project they are undertaking in cooperation with the city of Sunnyvale.

The project, called SSHIP (for Stanford/Sunnyvale Health Improvement Project), will be conducted by the Stanford Division of Cardiology and the Stanford Center for Research in Disease Prevention.

After conducting a telephone survey of randomly selected households, the researchers will focus their efforts on 400 relatively sedentary Sunnyvale men and women aged 50-64.

During the first year of the project some of these residents will participate in one of several different types of exercise programs while others will be asked not to change their exercise habits. Those participants assigned to exercise programs will either participate in supervised exercise classes or in one of two at-home or self-monitored programs organized around either high- or moderate-intensity exercise.

All of the participants will be evaluated at Stanford Medical Center at the start of the program, after six months and at the end of a year. These tests will determine the effects of the exercise program on cardiovascular endurance and many other heart disease risk factors such as blood pressure, smoking, cholesterol levels, body fat content, blood glucose and insulin and also measures of psychological stress.

Dr. William Haskell, associate professor of medicine, is directing the research project, which is funded by the National Institutes of Health. He said Sunnyvale, a city of 115,000, was chosen because its residents are representative of California as a whole.

In recent years there has been intense interest in the health and cardiovascular benefits derived from more vigorous exercise versus moderate-intensity exercise such as brisk walking.

Haskell notes that higher-intensity exercise has been shown to be effective for physical conditioning, but many adults do not care to exercise at this level. He suggests that moderate-intensity exercise might provide many of the same health benefits and that several researchers, including some at Stanford, have determined there is value in less strenuous exercise. However, he said, no one thus far has performed a study of the relative merits of moderate- and higher-intensity exercise on health status.

9-23-86 more

The project starts this month with a telephone survey of randomly selected Sunnyvale residences to find volunteers in the 50-64 age group who are sedentary, somewhat overweight and possibly smokers—in other words, the kind of people who would be expected to benefit most from an exercise program.

The researchers need 3,600 responses to the telephone survey. From these, 400 participants will be invited to volunteer for the next stage of the project. The volunteers, according to Haskell, will then be divided into four groups of 100 individuals:

- A group of self-monitored moderate-intensity exercisers, who work out at or near their homes.
- A group of self-monitored higher-intensity exercisers.
- A group of higher-intensity exercisers, who work out in a formal class setting conducted in the city of Sunnyvale.
- A group that will be asked not to change exercise habits for the next year.

The exercise intensity levels will be based on the heart rate achieved by the participants on a treadmill exercise test at the beginning of the project. Moderate-intensity exercises will bring the heart rate up to 50-60 percent of the maximal treadmill heart rate, while the higher-intensity exercises will aim at 70-85 percent of the maximal treadmill heart rate.

In addition to testing the fitness levels of participants three times during the first year, the research team will follow them through the second year to see if they continue to exercise.

Haskell said Sunnyvale officials have been highly cooperative in getting the project started and noted that there should be considerable benefit to the city and its residents aside from the examinations and physical conditioning of those who volunteer for the project. Some residents will be hired to conduct the telephone surveys; city organizations will receive information from the survey on the health needs and interests of Sunnyvale residents; and plans have been discussed to continue the successful aspects of the exercise program in Sunnyvale once the project is completed.

VOLUNTEERS SOUGHT FOR STUDY OF HYPERTENSION MEDICATION

STANFORD—

People with hypertension whose quality of life has been adversely affected by taking certain medications to lower blood pressure are being sought as volunteers for a study evaluating various kinds of medications.

The study is being directed by Dr. Peter Rudd, associate professor of medicine at the Stanford University School of Medicine. It is being conducted at the Palo Alto Veterans Administration Medical Center.

Volunteers must be between the ages of 18 and 60, in generally good health except for their hypertension and willing to make weekly visits to the VAMC for 14 weeks.

The researchers are looking specifically for patients who have used or are using Inderal (propranolol), Lopressor (metoprolol), Corgard (nadolol), Viskin (pindolol) or Tenormin (atenolol).

Those accepted for the study will receive free comprehensive medical and laboratory evaluation, free blood pressure medication and $10 per visit travel reimbursement.

Potential volunteers are asked to call Valerie Zachary, R.N., at 493-5000, extension 5918, between 10 a.m. and 2 p.m. weekdays.

SHUMWAY TO SPEAK AT LIVERMORE HOSPITAL ANNIVERSARY

STANFORD—

Dr. Norman E. Shumway, chairman of the Department of Cardiovascular Surgery at Stanford University School of Medicine, will be the keynote speaker at the 25th anniversary celebration of Valley Memorial Hospital in Livermore Sept. 28.

His topic will be "Four Decades of Open Heart Surgery." He will review the evolution of cardiopulmonary bypass operations, valve replacement and heart transplants.

The Sept. 28 celebration will feature a hospital-wide open house at Valley Memorial, 1111 East Stanley Blvd., Livermore. It will be the culmination of a month-long series of events to mark the 25th anniversary of the hospital.

Shumway is scheduled to speak at 2:15 p.m. on the front lawn of the hospital. A question-and-answer period will follow his speech.

STANFORD MEDICAL STUDENT RECEIVES FELLOWSHIP TO STUDY HEALTH CARE IN CHINATOWN

STANFORD—

Stanford medical student Chen-Tan Lin has received one of 34 SmithKline Beckman Medical Perspectives Fellowships nationwide for his study of the melding of Western and Chinese medical practices in San Francisco's Chinatown.

Lin is looking at the interaction of these two distinct traditions and how it affects the medical care of Chinatown's residents.

The $2,300 fellowship is administered through the National Fund for Medical Education. Lin has also received funding from the Stanford Medical Scholars Program, supported by the Stanford Medical Alumni Association.

More than 82,000 Chinese are living in San Francisco's Chinatown, Lin said. Many of these residents are suspicious of Western medicine and seek out Chinese medicine such as acupuncture and herbal medicine as well as crystals, cupping and other traditional Chinese practices.

Chinese medical practitioners are found only through word of mouth, Lin said. Through extensive interviews with patients and physicians, he is trying to determine what types of medical practices are available to Chinatown's residents. He is also looking at the qualifications of the practitioners and their attitudes towards alternative practices as well as what types of medical care are in demand and whether any integration of the two traditions is taking place.

The ideal situation, Lin said, would be if there were physicians schooled in both types of medicine, and who knew their limitations as well as when to refer patients to physicians from the other tradition.

With his project, Lin hopes to contribute to a method of integrating both types of medical care for the benefit of patients coming from different cultural backgrounds.

MAJOR MEDICAL CENTERS ARE BEST FOR HODGKIN'S DISEASE TREATMENT, ONCOLOGY EXPERT SAYS

STANFORD—

Although therapy and survival rates for Hodgkin's disease have improved dramatically over the last 20 years, patients should still be treated at major centers by experienced medical teams, said Dr. Saul Rosenberg, chief of the oncology division at Stanford University Medical School.

The proliferation of treatment to smaller hospitals and private physicians who do not see as many Hodgkin's patients is " at best a mixed blessing," Rosenberg said. The lack of experience, he explained, may increase the possibility of error in diagnosis and treatment with possible harm to the patient.

If patients do not come to major medical centers, he added, it also cuts back physicians' opportunities to research the causes of and ways to treat the disease.

Rosenberg, D'Ambrogio professor of medicine, reported on the current status of Hodgkin's disease treatment in a recent issue of Hospital Practice.

"No stage of the tumor is beyond cure," he said. "Every newly diagnosed patient can now be offered the probability of a cure; that probability is generally realized for three patients out of four treated at major cancer centers."

Hodgkin's disease is a cancer that strikes the lymphatic system, usually in people between 20 and 40 years of age. Once considered nearly always fatal, it is now curable in as many as 80 to 90 percent of patients with less advanced stages of the disease. Even those with more severe disease have as high as a 75 percent survival rate.

Long-term clinical trials involving hundreds of patients led by Rosenberg and the late Dr. Henry Kaplan account for much of the progress in treating Hodgkin's disease. Even so, "we do not know what is required to cause, reverse or prevent the disease," Rosenberg said. "Hodgkin's disease has long been recognized to have a number of peculiar characteristics, but most of them are still not fully understood."

Because of this, there is controversy about the different types of treatment and no established standards to manage patients. But, Rosenberg said, "all current programs that manage Hodgkin's disease effectively have one common aspect: they are complex, each demanding much from physician and patient alike. Experience is needed to treat the tumor properly. Equally necessary is a team approach, combining the special skills of surgeon, pathologist, radiologist, radiotherapist, medical oncologist and oncology nurse."

Hodgkin's disease is classified into four different stages dependent on its spread and severity. Each stage is treated by radiotherapy, chemotherapy or a combination of the two.

Kaplan was among the first to harness the power of the linear accelerator's powerful electron beams for the purpose of killing cancerous tumor cells in the early 1960s. Improvements over the years have led to more precise aiming of the beams so that nondiseased areas of the body are not affected.

Chemotherapy, on the other hand, involves various combinations of drugs, many of which are very potent and have adverse side effects. Physicians are continually testing new combinations and doses of the drugs to develop less toxic and more effective regimens.

Scientists are also researching new methods of treatment for Hodgkin's disease such as bone marrow transplantation and monoclonal antibodies, Rosenberg said.

EMERGENCY DEPARTMENT DOCTOR GOES TO AMERICA'S CUP

STANFORD—

The top contenders in the America's Cup Yacht Race will have a Stanford Medical Center doctor for two weeks starting in late October.

Grinder's elbow isn't among the more common maladies Dr. George L. Sternbach regularly treats in the Stanford University Hospital Emergency Department, but he says he is ready for such problems when he arrives at the race trials in Perth, Australia.

Sternbach, 40, is deputy director of emergency services and medical director of the institution's Life Flight emergency helicopter service. He was one of nine emergency physicians selected from more than 50 applicants for two week stints Down Under, said Dr. Thomas Kravis, director of the Department of Emergency Care at Mercy Medical Center in San Diego. The team physicians will be working for Sail America, the San Diego syndicate sponsoring top rated contender Dennis Conner's challenge for the Cup in January.

The 138-year-old race is perhaps yachting's most prestigious event. Private sponsors spend millions of dollars to mount teams and specially constructed 12-meter yachts for the event once every three years.

In 1983, Conner skippered the first American loss in 132 years, sending the event's prize, the Cup, from the New York Yacht Club to the winner's home club in Perth.

Kravis believes that the team physicians are key players in the crew and support effort to bring the cup back from Australia. The Sail America team includes some 70 persons, including a sports therapist. How was Sternbach selected for this assignment?

"Tom Kravis asked me about a year and a half ago if I were interested," Sternbach explained. I knew him from having written two chapters for the book he edited, *Emergency Medicine—A Comprehensive Review*.

Those chapters were about pulmonary edema and dermatology. Expertise in the latter might come in handy for treating sunburn as the south of the equator sun moves the temperature toward the 100-degree mark, says Sternbach, but "these guys have been training in the sun for a long time, and they're probably quite knowledgeable about sunburn already." Both he and Kravis believe that orthopedic injuries will take up the bulk of team physician time.

9-22-86

more

Kravis says that 12-meter racing produces some specific injuries. For example, one crew member continually operates a winch and is prone to what's called grinder's elbow, similar to tennis elbow. Another crew member is responsible for keeping sails and must risk back injuries by stooping at a 90 degree angle in the cramped quarters below deck. The skipper gets to stand and shout orders, but even he is prone to tendonitis of the wrist from steering.

Sternbach said he has in fact crewed on some Great Lakes races at the time he started in emergency medicine in Chicago before coming to Stanford nine years ago.

But Sternbach said that was pretty low key racing, although some of his fellow crew eventually went on to bigger and better racing. "Maybe it was my encouragement," he jokes. He hopes some of that enthusiasm will help the U.S. sailors in Perth.

What else has he done for excitement? It's been a long time, 32 years, since the event Sternbach described as the most exciting of his life. In 1952, he and his family escaped under cover of darkness from Czechoslovakia, to begin a new life in the West and ultimately in the United States.

Sternbach, who received his M.D. from the University of Michigan Medical School in 1972, has had a lot of experience as a team physician, serving at auto races in his Chicago years. As acting director of emergency services in 1985, he was responsible for emergency care at the site of the Super Bowl at Stanford Stadium.

Kravis said the Australian government passed legislation enabling a U.S. physician to treat Americans during the course of the race. He said the Sail America syndicate decided to bring its own doctors to ensure that treatment was quickly available at the race site.

Sternbach and his fellow doctors are part of the Sail America syndicate, but they will be available to treat the four or five other American teams during the trials that precede January's finals, Kravis said.

PLASTIC AND RECONSTRUCTIVE SURGERY IS SUBJECT OF FALL PUBLIC LECTURES

STANFORD—

"More than a Pretty Face—The Fine Art of Plastic and Reconstructive Surgery" is the topic of a three-part evening lecture series open free to the public at Stanford University Medical Center.

Theme of the fall Progress in Medicine series, say organizers, is to show that plastic and reconstructive surgery goes far beyond reshaping noses and performing face lifts. Surgeons spend most of their time reshaping the damaged body and restoring its proper function using a variety of state-of-the-art medical approaches.

Each Tuesday evening features two speakers starting at 7:30 p.m. at Sherman Fairchild Auditorium at the Medical Center.

•Oct. 7, "Plastic and Reconstructive Surgery: Beyond Fixing the Body Image," Dr. Lars M. Vistnes, professor and head of the division of plastic and reconstructive surgery at the Medical Center; and "The Art and Science of Mending the Hand," Dr. Vincent R. Hentz, professor and head of the division of hand and upper extremity surgery.

•Oct. 14, "Plastic Surgery after Mastectomy," Dr. Seung K. Kim, assistant professor of surgery; and "Mirror, Mirror on the Wall," Dr. Robert M. Pearl, clinical associate professor of surgery and assistant physician-in-chief, Kaiser Permanente Hospital, Santa Clara.

•Oct. 21, "The Future of Microsurgery," Dr. Joseph M. Rosen, assistant professor of surgery and chief, division of plastic surgery, Palo Alto Veterans Administration Medical Center. Then Dr. Donald R. Laub, clinical associate professor of surgery, will discuss "The Interplast Story," the international group Laub was instrumental in forming which sends physicians and other medical personnel to help impoverished victims of birth defects or other deformities in developing nations.

Parking is free at the lot which is located at the extreme west end of the Medical Center near Campus Drive. Although these community outreach lectures are free, organizers would appreciate receiving reservations to help with planning. To RSVP, or for further information, call the Medical Center Office of Public Events, (415) 723-6389.

LIFE FLIGHT SERVICE GETS NEW HELICOPTER

STANFORD—

A spacious new helicopter that can be easily adapted to specific medical needs arrived this week at Life Flight, the emergency medical helicopter service shared by Stanford University Hospital and Santa Clara Valley Medical Center.

The new helicopter is a twin-engined BK 117 designed and developed by Messerschmitt-Boelkow-Blohm. It is owned and operated by Rocky Mountain Helicopters, Inc., of Provo, Utah, and leased by Life Flight—the same arrangement as that for the TwinStar used by the emergency service until now.

Life Flight began operations in May, 1984, and made its 1,000th flight just last week.

Marcia Katz, chief flight nurse for the program, said the BK 117 has a cruising speed of about 160 miles an hour and a range of about 150 miles—approximately the same as the old helicopter. Its chief advantage, she said, is in added space and flexibility for medical use.

"There is room for five members of the medical crew with a critical patient or two medical crew members and two patients," she said. "There is also more working space for taking care of trauma patients."

Dr. Michael Eliastam, director of the Life Flight program, described the BK 117 as "a flying emergency and critical care unit that enables us to accomplish all the missions of the medical center, including high quality care in a setting where research and teaching can occur. The aircraft is big enough for training and/or research data collection."

Katz also pointed out that the BK 117 can be used for the specialized missions of both Stanford and SCVMC.

"Stanford might require a complete transplant team to accompany a donor candidate or organ recipient," she said. "Or Santa Clara Valley could need specialized medical equipment on board for a patient with a spinal cord injury. Both of those needs can be easily accommodated with this helicopter."

She noted that the pilot of the BK 117 is completely isolated from the medical team. "We find this to be much safer than having the patient intrude upon the cockpit area," she said.

Life Flight is now averaging about 45 to 50 missions a month. It is always staffed by a trained flight physician and a flight nurse.

September 4, 1986

Dr. Lawrence Simon has been appointed acting chief of Medical Service at the Palo Alto Veterans Administration Medical Center, effective-September 1, 1986. This appointment had been held by Dr. Ferid Murad, who has accepted a position as acting chairman of the Department of Medicine at Stanford University.

Dr. Simon has been at the VA Medical Center since 1974, and has served as chief of the Respiratory Disease Section since 1979. Additionally, he has been a member of the Stanford University faculty since 1974; he is now an associate professor of medicine at the university.

A Los Altos resident, Dr. Simon received his medical training at the University of Miami School of Medicine.

The VA's Medical Service consists of such divisions as hematology, cardiology and gastroenterology. The service includes 30 doctors and 29 house staff who oversee 75 hospital beds and 100,00 outpatient visits a year.

NEW BOOK CHRONICLES AFRICAN PYGMIES' HEALTH, GENETICS AND WAY OF LIFE

STANFORD—

A single shot of penicillin could cure African Pygmies—the world's smallest people—of one of their major health problems, says a Stanford University geneticist.

Approximately 50 percent of Pygmies have yaws, an infectious skin disease, that could easily be treated with one shot of penicillin each, says Dr. Luigi Luca Cavalli-Sforza, genetics professor at Stanford University School of Medicine.

But because the world's 150,000 to 200,000 Pygmies live deep in the forests of tropical Africa, it would require a well-organized and well-funded medical relief effort to distribute the antibiotic to the entire population, adds Cavalli-Sforza, who is presently searching for a sponsor for such an undertaking.

Cavalli-Sforza, who has studied the Pygmies for 20 years, is the editor of a new book about the Stone-age people, called *African Pygmies* (Academic Press Inc., Orlando, Florida, 1986, 461 pages).

The book summarizes a large amount of biological and anthropological information gleaned from several expeditions during the last 20 years to Cameroon, the Central African Republic, Zaire and other African nations where the Pygmies live.

Scientists are interested in Pygmies because they are the shortest people on earth, with an average height of about 58 inches, or just under five feet.

But perhaps more significant, says Cavalli-Sforza, is the fact that African Pygmies are among the few groups of "hunter-gatherer" societies remaining relatively untouched by the modern world and living in much the same way as humans are believed to have lived more than 10,000 years ago.

Pygmies live in small groups of about 30 in the forest, erecting temporary camps of leaf-and-branch huts. They are semi-nomads who migrate through the forest in quest of game and other food, clad only in loincloths of bark or cloth.

Sometimes Pygmies emerge from the lush forests to trade with farmers or villagers on the outskirts, but "perhaps one of the most remarkable phenomena is the persistence of the Pygmy way of life for 2,000-2,500 years" despite this contact with the more modern world, Cavalli-Sforza notes in the book.

Although central Africa's tropical forests have been receding as the climate dries and farmers slash and burn the vegetation to make way for agriculture, further investigation of the paleolithic way of life among Pygmies can still take place and should be encouraged, Cavalli-Sforza suggests, before they are completely acculturated into the modern world.

The scientists who contributed to the book all found the Pygmies highly cooperative in the research efforts and extremely pleasant to work with, Cavalli-Sforza notes. Much of the research consisted of observation and interviewing Pygmy groups in remote jungles, as well as taking blood samples for later laboratory-based genetic and medical studies.

9-9-86 -mor

The book lays out in detail the genetic analyses of blood groups, enzymes, and other hereditary markers which prove that the Pygmy groups that haven't had recent admixture have been isolated from other populations since ancient times, perhaps 10,000 to 20,000 years.

The book also presents a wealth of physical and medical data about Pygmies.

Probably of greatest interest is the information about Pygmies' short stature, which has been a subject of speculation for years, Cavalli-Sforza observes.

Their diminutive size now is attributed to a deficiency of somatomedin-C, a protein that in recent years has been shown to stimulate skeletal growth under the influence of growth hormone. The Pygmies' typical short stature first becomes apparent in their early teens when, unlike most other humans, they experience almost no post-pubertal growth spurt.

Although the shortness is genetic, the exact nature of its inheritance—recessive or dominant, a single gene or multiple genes—is not clear, Cavalli-Sforza points out. But with new techniques of molecular genetics, he and his colleagues may be able to home in on the precise genetic elements involved in an effort to answer the remaining questions.

Scientists can only speculate about why Pygmies have remained short when most other humans became taller over evolutionary time. Cavalli-Sforza and his colleagues argue, in the book, that being short is a beneficial adaptation to their hot, humid forest habitat. A small body, the scientists explain, does not generate as much internal heat and thus enables the Pygmies to stay cooler in the sweltering climate.

The scientists conclude that Pygmies tend to be fairly healthy considering their reliance on witchcraft, lack of access to modern medicine, and occasional malnutrition. However, they do suffer from heavy parasitic loads that could be reduced if they were taught some simple rules of hygiene, the book suggests.

In addition, the scientists suggest that poor hygiene and lack of clothing may contribute to the spread of yaws and other infectious diseases, such as diarrhea and respiratory infections, which appear to be the major causes of death among Pygmies.

The book also discusses what is known about the Pygmy way of life and rituals, including marriage, contraception, childbirth, and pubertal rites and practices.

Among the more than 30 contributors to the book are noted anthropologist Colin Turnbull and geneticist Walter Bodmer.

Cavalli-Sforza added in an interview that the work that began with the Pygmies is now expanding to include other rare human populations. In the last two expeditions to collect blood samples from the Pygmies (in 1984 and 1985), Cavalli-Sforza retrieved samples for "immortalization."

"This is a treatment of certain white blood cells with a virus which makes them capable of indefinite multiplication in the laboratory," he explained. "In this way it will be easier to apply the new techniques of molecular genetics for a study of these unique populations."

Cavalli-Sforza is collaborating with Yale genetics professor Ken Kidd to extend these techniques to other populations.

"Many of these are on the verge of extinction, usually because of loss of identity, and like Pygmies, they represent very different evolutionary directions and adaptations of the human species," he said. "This bank of disappearing populations will be invaluable for studies of human evolution and history."

CONSTRUCTION TO CAUSE BRIEF DETOURS NEAR MEDICAL CENTER

STANFORD—

A portion of Blake Wilbur Drive adjacent to the Stanford University Medical Center will be closed for about five days beginning Monday, Sept. 15.

The closure is necessary to complete work on trenches for sewers connecting to Stanford's hospital modernization project (HMP). The portion of the road affected will be the 300 feet from Quarry Road to the edge of the HMP work site.

The work will be done in two stages to allow continued use of the parking lot at the Cardiovascular Research Building at the corner of Blake Wilbur and Quarry.

Through traffic between Blake Wilbur and Quarry will have to detour along Welch Road or Campus Drive until the trenching is completed.

GENETICALLY ENGINEERED HUMAN-GROWTH HORMONE MAY HAVE MULTIPLE USES, STANFORD SCIENTIST SAYS

STANFORD—

Now that a genetically engineered human-growth hormone is available in ample supply, physicians have been able to begin researching its potential uses other than treating abnormally short children who lack the real thing. Like the children under treatment, the possibilities continue to grow.

Preliminary work at Stanford University Medical School has shown that growth hormone can help children with Turner's syndrome, a rare chromosomal abnormality that causes problems including short stature, according to Dr. Raymond Hintz, Stanford pediatric endocrinologist.

Physicians are also looking into possible benefits for children whose growth is delayed but eventually normal, a condition called constitutional growth delay, and for the elderly. They're looking at ways the hormone can promote wound healing and bone growth following fractures as well.

Nearly 4,000 children whose pituitary glands fail to produce the hormone, which is responsible for growth, are now being successfully treated with the synthetic drug. But, Hintz said, at least another 4,000 undiagnosed hormone-deficient children could benefit from treatment.

"One of our goals is to increase the awareness among parents and physicians that the hormone treatment is available and is effective for some severely short kids," Hintz said.

Aiding in this effort is Human Growth Week, designated as Sept.7-14 by President Reagan and sponsored by the Human Growth Foundation.

The Food and Drug Administration (FDA) approved the man-made version of the essential hormone nearly a year ago, just in time to replace the scarce naturally made hormone, which can be obtained only in minute amounts from the pituitary glands of cadavers. That hormone is no longer used because of a fatal virus it possibly contained.

Natural growth hormone is secreted by the pituitary gland, a tiny organ at the base of the brain. It is released in spurts into the body, triggering growth during a child's pre-pubescent years. Once the bones have stopped growing during puberty, the hormone no longer functions although it is still produced.

Children whose pituitary glands do not produce the hormone, due to hereditary factors or illness, are significantly smaller than normal, which can cause social and psychological problems. By treating them with the synthetic hormone however, they can quickly catch up to other children in their age group.

The man-made hormone, called Protropin, was first synthesized in 1976. Scientists were able to determine the sequence of amino acids of the protein, duplicate it through recombinant DNA techniques and then clone it in mass quantities in the laboratory.

While its availability has allowed scientists to study the hormone, it has also placed them in a race against time. Only one company, Genentech, is presently making the hormone. The San Francisco-based company has limited distribution of the drug in order to keep track of how it's being used. But, Hintz said, several other companies are developing similar drugs; one could become available as early as next year. The more growth hormone available, the less control. And the less control, the more potential for abuse of the valuable drug.

"We're anxious to find out more about what else it will do and will not do," he said. The more research we can get done before the distribution expands, the more we can cut down on some of the misuse."

Opportunities for misuse, Hintz explained, are plentiful. The hormone has a beneficial effect on protein metabolism—it helps the body conserve proteins that help build muscle mass. This quality is what may prove useful in helping the elderly, whose hormone production diminishes over time, avoid some of the deterioration effects of aging. It may also promote healing and guard against muscle atrophy for patients who have temporary physical limitations. But it's also the quality that athletes looking for that "extra competitive edge" may be willing to risk taking the drug for, even though its effectiveness hasn't been proven.

And then, he added, there are always parents who wish their children were just a little bit taller. "You have to sort out those who will benefit from treatment and those who won't. We're looking at select people, we're not interested in growing a basketball team."

Significant amounts—as much as 20 percent—of the natural growth hormone were "diverted" from its proper use, Hintz said. Only one mishap has taken place with the synthetic hormone—about $250,000 worth was stolen from a distributor earlier this year.

The treatment is not cheap; it can run up to $15,000 a year. Most insurance companies, MediCal and Crippled Children's Services (CCS) cover the treatment for children with growth hormone deficiency. Genentech is picking up the tab for any children not otherwise covered, Hintz added.

"I hope other uses are found for the hormone because as it becomes more commonly used, the price will drop," he noted.

STANFORD AND UC RECEIVE JOINT AWARD FOR COHEN-BOYER PATENT

STANFORD—

Stanford University and the University of California will receive a special award Sept. 8 from the American Chemical Society (ACS) for their cooperative activity relating to a gene-splicing patent which helped spark the biotechnology industry.

The award is being given to the licensing and patent offices at both universities for their combined efforts to license a patent on gene-splicing and cloning processes developed jointly by genetics professor Stanley Cohen of Stanford University School of Medicine and biochemistry professor Herbert Boyer of UC-San Francisco.

Licenses offered under the patent allow private firms to obtain rights to use the patented techniques in developing products and processes for public use and benefit.

Nearly 80 firms are now licensed to use the Cohen-Boyer techniques. Commercial recombinant DNA applications have led to the development of human insulin, vaccines for hepatitis B and livestock diseases, and a growth hormone to combat dwarfism.

The ACS's intention is "to recognize the patent and licensing offices at both universities for their cooperative efforts, which we believe established and continue to foster the emerging biotechnology industry in the United States," said Dr. Howard Peters, co-founder and councillor of the ACS Division of Chemistry and the Law.

Niels Reimers, director of technology licensing at Stanford, Katharine Ku, associate director, and Roger Ditzel, director of UC's patent, trademark and copyright office, will receive the award at the ACS's 192nd annual meeting in Anaheim.

HOSPITAL DIETITIANS OFFER WEIGHT CONTROL PROGRAM

STANFORD—

A personalized weight loss plan, low calorie cooking demonstrations, recipes and menu planning are featured in an eight-week weight management course offered at Stanford.

Guest speakers will discuss stress reduction, behavior modification techniques, and exercise, dietitian Diane Madgic said. A special feature is instruction on techniques for wise ordering while dining out.

Entitled "An Enlightening Experience," the course is offered by the Stanford University Hospital Department of Dietetics. Evening sessions, each Tuesday night from 7:30 to 10 p.m., run Sept. 23 to Nov. 11, while daytime sessions, Thursdays from 1 to 3:30 p.m., start Sept. 25 and end Nov. 13.

Participants must preregister for sessions, which are held at Stanford Medical Center, by calling (415) 723-6904. Enrollment is limited.

Madgic said the fee is $325 with a $50 refund if the individual's weight goal is reached.

PARTICIPANTS NEEDED FOR HYPERTENSION RESEARCH

STANFORD—

Volunteers are being sought by researchers at the Palo Alto Veterans Administration Medical Center for studies of metabolic changes that may be associated with hypertension, or high blood pressure.

The researchers are investigating the possibility that some of these metabolic changes may be risk factors for coronary artery disease.

People with normal and high blood pressure are both needed for studies of possible similarities between hypertension and diabetes mellitus. Volunteers with high blood pressure are also needed for a study exploring in detail a possible beneficial effect on cholesterol of prazosin, a commonly used antihypertensive.

The studies will take place at the Aging Study Unit at the VAMC, under the direction of Drs. Gerald Reaven, Brian Hoffman, Arthur Swislocki and their associates. Reaven is professor of medicine at the Stanford University School of Medicine.

Anyone interested in participating in the study is asked to call (415) 493-5000, ext. 4572, between 9 a.m. and 5 p.m. Monday through Friday.

Two drugs that have shown promise in slowing the progress of Alzheimer's disease are being tested by researchers from the Palo Alto Veterans Administration Medical Center and Stanford University.

In a six-month study using 55 volunteers in the early stages of the disease, the drug ACTH 4-9 is being administered in higher doses than previously studied. The drug is a synthetic hormone fragment and works chemically on the way nerve cells communicate with each other. The drug has been very effective in improving memory in rats.

The study, which is nearly complete, is double blind so researchers do not know which participants are receiving the drug; however, some of the study participants have shown improvement, researchers say.

The second drug to be tested is Hydergine, a metabolic enhancer that improves the way nerve cells use glucose. The drug has been approved by the FDA for use in certain doses, although it has never been conclusively shown to be effective. The study will use doses three times higher than currently approved and will follow the patients over the course of a year. Volunteers are currently being recruited for this study.

Alzheimer's disease is the progressive loss of intellectual functioning caused by changes in the brain. The disease is estimated to strike between 600,000 and 1.2 million Americans over the age of 65 and kills approximately 100,000 annually. At the present time there is no cure or treatment.

Researchers are available for interview. For more information, call (415) 493-5000 ext. 4778 or 4780.

WHO WILL CARE FOR ALL THESE PEOPLE? THE EFFECTS OF CHANGES IN HEALTH CARE POLICY

STANFORD—

A revolution is taking place in the health care field, and it's resulting in some changes in the way you may be treated the next time you seek medical care.

- If you're not yet one of the approximately 30 million Americans enrolled in a prepaid health insurance program, chances are you'll be joining one soon.
- As a member of such a plan, you may find your choice of physician or hospital limited according to those who honor your health care coverage.
- You may receive "less" care for a medical condition than you would have, say, five years ago.
- The care you do receive may be at one of the mushrooming number of outpatient or ambulatory care facilities instead of in a hospital.
- In the event that you are hospitalized for a procedure, more likely than not you'll be out of the hospital sooner than you would have been five years ago.
- You may be asked to pay for a larger portion of your medical care out-of-pocket.
- If you live in a rural area, your local hospital may have closed. If so, chances are that most, if not all, physicians have taken their shingles elsewhere. Thus, you may have to travel significantly farther distances to receive medical care.

These changes may be inconvenient, but as a member of the middle or upper classes in this country, you do have access to medical care. But if you're among the elderly, the fastest growing population group in the country, health care coverage may be increasingly costly and necessary services may be hard to come by. And if you're one of the approximately 30 million poor or uninsured, your access to health care may become extremely limited.

The health care revolution is spurred by spiraling health care costs, now estimated at nearly 11 percent of the total amount of the U.S. gross national product. Panicked by predictions of those costs topping $660 billion by 1990 and reaching $2 trillion by 2000, the federal government has declared a war of sorts. It has come up with new payment methods and has slashed program budgets in an effort to eliminate the "fat" in the health care system. The federal government set the example; state governments and private payors of health care, from insurance companies to individual employers, have followed suit. The goal? To cut costs without sacrificing the quality of care.

To some extent, it's working. Hospital administrators and physicians have taken a hard look at the health care industry, scrutinizing every aspect from the organizations they've established to the way individuals practice their trade. They've eliminated hospital programs not directly related to patient care; they're finding more efficient, and economical, ways to provide medical care. In some cases, they admit, the changes they were forced to make have resulted in better care.

But in the process, a few groups of people — namely the poor, the uninsured and the elderly — are falling through the cracks in this newly evolving health care system in which competition and the concept of a "medical marketplace" are key. Physicians and health care experts agree that these are problems that the government and society haven't yet begun to tackle. "The system is not reacting fast enough to meet the needs of society," says Dr. James Silverman, former chief of staff at Stanford hospital.

In their efforts to save dollars, government decisions are leading American society to shirk its social responsibility by not providing these people access to even the most basic medical care.

"We are on the borderline of a health care crisis," says Robert Sillen, executive director of Santa Clara Valley Medical Center, one of California's county hospitals. "In the next two years or so, people will start asking how we, the richest society in the history of the world, can treat the most vulnerable segments of our population in a totally unacceptable manner." This won't happen, he says, until people have "more awareness of the increased numbers of people having significantly untoward events, including death, from a lack of access to the kinds of medical care that historically have been available."

At first it was just anecdotal: a patient refused care at one hospital and "dumped" into another; another patient discharged too early, resulting in further illness; yet another patient denied medical care all together. But slowly, substantial evidence of a growing dissatisfaction with the health care system is mounting, as the following examples illustrate.

- Results of a Louis Harris Poll done in New York City, released last June, found that increasing numbers of the city's poor are being denied health care except at government-designated facilities.
- A Johns Hopkins School of Hygiene and Public Health study, released last May, concluded that because of lack of access to the medical system, blacks who reside in Maryland are less likely to undergo surgery for health problems than their white counterparts.
- A California Poll, released last July, found that among families with incomes of less than $10,000 a year, 42 percent said they had not seen a physician when they were sick because of the expense.

Nationwide, the goverments' main targets for lowering health care costs have been Medicare and Medicaid, programs that were introduced in the 1960s to insure medical coverage for all Americans, regardless of economic status. Eligibility requirements have been tightened, cutting the proportion of low-income Americans insured by Medicaid from 63 percent to 46 percent. Congress is allocating an increasingly smaller amount of the federal budget to fund the programs; it has given preliminary approval for a $3.2-billion cut in Medicaid during the next three years.

California's MediCal program, which covers the state's poor, has instituted comparable cuts. In addition, in 1983 a group of patients classified as medically indigent adults, or the "working poor," were assigned to state-supported county hospitals for care. Any other hospital treating such a patient is no longer paid for the services unless it has a contract with MediCal.

Most significantly, the federal government in 1983 came up with a new way to pay for health care. This new method, the prospective payment system, set the price hospitals are paid *in advance* for the care they give, a radical departure from the traditional fee-for-service system. By doing so, the reasoning went, reimbursement could be standardized across the country and capped.

Private payors of medical care followed the governments' example. Aside from adding a multitude of acronyms to the English language, prospective payment has taken health care in a new direction, one that includes competition for patients and contracts that bind patients to specific physicians and health care facilities. The emphasis is increasingly on preventive health care and on decreasing usage of hospitals and, in many cases, physicians.

"We started with relatively fat organizations across the country that had lots of services not directly related to patient care," Silverman says. With less reimbursement coming in, "hospitals are deleting those services that are least important to patients.

"The changes in reimbursement have been very effective for Medicare patients," he adds. "In fact, they've driven down the total cost of health care."

Patients may enjoy the prospect of getting lower medical bills, but taking the "excess" out of the health care system may have long-range effects that may do more harm than good.

One such effect is the so-called "commercialization" of medicine. Stanford hospital is "a sleeping giant," says David Sakai, director of finance. Because of its fame as a teaching hospital and as a tertiary care center, it has never before had to market itself or compete for patients. In this new environment, however, "we realize that just being Stanford is not enough."

In order to stay viable, in recent years Stanford, like most hospitals, has aggressively gone after groups of patients. For example, it has signed contracts to provide care at reduced costs for MediCal, which may pay about 50 cents per each dollar of care provided, private insurance companies and even large local industries. No longer is it unusual to see an advertisement for a hospital, or to hear about gimmicks such as VIP rooms and special menus instituted to help attract patients. But even the increased emphasis on marketing fails to compensate for more substantial changes in medical practice.

more-

Not only are payors paying less for medical care, but patients are receiving "less" care as well. Physicians traditionally have had a tendency to overtreat, says Dr. John Bunker of the family, community and preventive medicine department, partially for fear of malpractice and partially because of patients' desires and expectations that "everything possible be done." Now, they have started to be more selective in ordering diagnostic tests and procedures as well as in the treatment they give. Medical students are trained in decision-making; Stanford medical staff now carry a pocket-sized list of the charges for all tests to raise their cost-consciousness.

And, partially because of advances in medical technology, more treatments are being done on an outpatient basis — in urgent care centers, surgical centers, ambulatory care centers, rehabilitation institutes, freestanding diagnostic centers, hospices, alcohol treatment centers and through home health care services, says Robert Blendon, senior vice president of the Robert Wood Johnson Foundation. He estimates a further decline in hospital admissions of 15 percent — and as much as 20 percent for people under age 65 — by 1995. Combined with a continuing decrease in the length of time patients stay in the hospital, he predicts as many as 100,000 to 200,000 unused hospital beds by 1995. "This is the equivalent of about 1,000 average-sized community hospitals standing empty," he notes.

In a letter to all employees earlier this year explaining the need to "downsize," Sheldon King, Stanford hospital's president, explained the institution's predicament. "From 1982-83 to 1984-85, our average daily census fell from 429 to 385; the average length of stay dropped from 6.8 to 6.3 days; and patient days went from 156,654 to 140,552."

This translates into nearly $20 million lost because of reduced patient revenues, reduced government reimbursements and prepaid, discounted care contracts, King says.

"Physicians' practices are changing," Sakai observes. For example, removing cataracts used to be the most commonly performed procedure in the hospital, he explains. Now, it's done on an outpatient basis.

Even though it's providing less care to fewer patients, Stanford has come out slightly ahead under the new reimbursement rules. But, Sakai warns, that won't last. Medicare's new system, in which all patients are classified according to their illness into diagnostic related groups, has been phased in over a four-year period. Variances in reimbursement were allowed for differences in cost, dependent on geographic location. Teaching hospitals, such as Stanford, were reimbursed at a higher rate because its patients are usually sicker and require more care, and because of the added expense of their educational programs. But next year all rates will be standardized. And in California, where salaries and other costs of providing care are significantly higher than in other areas of the country, hospitals are sure to suffer. What's more, the news that a majority of hospitals saw increased revenues in recent years has prompted the government to freeze Medicare rates with only a one-half percent increase scheduled for next year. "Meanwhile our operating costs are going up 6.9 percent," Sakai says.

Discrepancies in the rates patients pay for health care have always existed, but hospitals have always been able to "cover" for those who paid less, or didn't pay at all, with those who paid the full amount. But with the number of patients paying full cost shrinking, "the clamps are on," Sakai says, and Stanford's "moral" commitment to providing care to all who need it is being affected by financial considerations.

For example, despite the fact that Stanford is in a relatively affluent area, and serves a relatively low Medicare population of about 33 percent of its total patient population, Stanford's bad debt—costs run up by care given to patients who are uninsured and can't afford to pay—has "increased dramatically," Sakai says. About $300,000 in 1982, this year it tops one million.

"We swallow the costs on patients who need our special kinds of care and come here but can't pay," Silverman says. "When push comes to shove I can't turn away a patient who needs unusual treatment. But if they can be treated elsewhere appropriately, they should be."

Silverman's "elsewhere" is a public county hospital, charged by the state to provide care for the poor. Unlike Stanford and other private hospitals that have experienced declining numbers of patients, however, county hospitals, such as Santa Clara Valley Medical Center (SCVMC), are bursting at the seams.

Since 1983, admissions to the 469-bed hospital have increased 61 percent, according to Ann Moses, assistant to executive director Sillen. "We've literally run out of beds on numerous occasions this year," she exclaims. Patient visits to the clinics and emergency department have gone up 63 percent. Staff, however, has increased only 11 percent.

more

"Our primary cost containment effort has been holding the line on staff and absorbing increased volume," Sillen says. "We haven't compromised the quality of our care, but the experience patients have with the hospital has suffered. Patients wait as long as six hours in the clinics now. They complain, staff complain, I'm complaining, too. Everyone is trying to do the best they can, but we cannot produce if we do not have the resources to produce with."

Unlike private hospitals that can refer patients to county hospitals, SCVMC has no other institution to turn to. Over the past few years, Moses says, the bad debt has skyrocketed to 30 percent of the hospital's gross revenue.

"Nobody's competing for my uninsured patients," Sillen says. "Nobody's competing for the poor Medicare patients. Government is advocating a competitive market for health care. Well, General Motors doesn't give away cars to people who can't afford them. The same goes for health care. If this country wants to consider health care services in the same manner as the production of autos, we're in serious trouble."

While Sillen and others are continuing to operate in an environment that "is only going to get worse," health policy experts are grappling with the question of how to provide medical care to all Americans in an economically feasible way. Most experts agree that a national health insurance scheme isn't viable in the United States. Yet other ideas, however preliminary, are beginning to surface.

Alain Enthoven of Stanford's business school advocates a system in which people are forced to be more conscious of health care costs. He proposes a scheme in which employer contributions for health insurance are added to an employee's taxable income. In return, each individual would receive a tax credit with which to buy health insurance. Anything above that amount would come out of the individual's pocket. Stanford health care economist Victor Fuchs, of the National Bureau of Economic Research, has proposed that people buy only "catastrophic" insurance to cover major illnesses and pay for everything else out-of-pocket.

But what about people who are not employed? Dr. Ralph Schaffarzick, senior vice president and medical director of Blue Shield of California, describes another plan, one that is already being experimented with in some states. "Currently the best answer seems to be the creation of a risk pool," he explains. The uninsured and poor people should be divided up among all insurers, he says, so all would be collectively responsible for those who could not pay for their own health care. Countless other proposals will undoubtedly be considered before a solution is found.

In an article published earlier this year, Fuchs asks, "has cost containment gone too far?" The answer may not be available for years to come. But, says Dr. Kenneth Kizer, California's state health director, the current revolution is providing the opportunity for the medical profession to "go back to the drawing board and reexamine some basic questions as to how medicine should be practiced. The whole focus of care is changing.

"There are going to be some troubled times and a lot of changes. Just wait," he says, "you 'ain't seen nothin' yet."

The precarious position of teaching hospitals

Like all teaching hospitals, Stanford is in a more vulnerable spot than most other institutions when it comes to surviving in a cost-conscious, competitive yet regulated health care environment. Besides providing medical care to patients, they have some additional roles. Teaching hospitals are a source of advances in technology and procedures. They are responsible for training future physicians. They have also traditionally provided a major portion of care to the poor and uninsured. These functions, however, are not cheap.

One of the largest expenses teaching hospitals incur is the cost of training physicians. As interns and residents, physicians-in-training do provide care to patients for which they are paid much lower stipends than faculty physicians. But they must work under faculty supervision, and sometimes they order tests or procedures more for the educational value than patient benefit. These are essential as part of their training, but costly.

It's also essential that future physicians are exposed to as many types of patients as possible. To satisfy this need, teaching hospitals attract not only those with rare diseases, who come to receive the latest available treatments, but also the poor and uninsured who need more routine care. In fact, members of the Council on Teaching Hospitals of the Association of American Medical Colleges provide nearly 50 percent of all charity care and about 33 percent of all bad debt care, even though they account for only about 20 percent of the nation's hospital beds.

For example, about 30 percent of Stanford's neonatal and obstetrical patients are among the poor or uninsured. "Not only do we have a moral commitment to treat these people, but we need them for our teaching program," says David Sakai, director of finance at Stanford hospital.

In the past teaching hospitals have been able to "cover" these extra costs by spreading them around to all patients. But with the emphasis on reducing costs, that is getting more difficult to do.

"The central problem facing academic health centers is that the care rendered by their teaching hospitals is more expensive than that rendered by their nonteaching counterparts," writes Dr. Neal Vanselow, vice president of health sciences at University of Minnesota, in the summer 1986 issue of *Issues in Science and Technology*. A Commonwealth Fund Task Force found in 1981 that the mean cost for each patient discharged from major teaching hospitals was more than twice that for nonteaching hospitals.

"Unless policies can be formulated to reflect the unique needs of academic health centers, and unless the centers can adapt to the new environment, the future of these vital institutions is by no means assured," Vanselow says.

Cutting the costs of medical care

In an era where "less is better," Stanford is doing all it can to cut the costs of medical care without affecting the quality. Some actions have had an immediate impact, such as the hospital's "downsizing" earlier this year in which about 150 employees not directly related to patient care were laid off. Administrators and physicians are going further, however, delving beneath the surface of medical practice to see if, in fact, there is a better way to do their job.

With funding from the Kellogg Foundation, former chief of staff Dr. James Silverman is leading teams of physicians, nurses, and medical technicians from different specialties in looking at specific areas of patient care for ways to contain costs. For a specific urology procedure, for example, a group found they could decrease the number of tests they ordered without compromising the care of the patient. Those involved with the orthopedic surgery group found that for total hip replacement patients, some preoperative testing and two days of hospitalization could be eliminated, thus saving as much as $2,000 per patient. A group looking at a coronary angioplasty procedure, however, recommended that no changes be made.

Other cost-containment projects involve managers, who are given data about specific units from hospitals all over the country. With the data, they can see if comparable services have comparable costs, and make any indicated changes.

"Regionalizing" care may also lead to reduced costs, many experts believe. Recent studies, for example, have shown that patients who undergo heart bypass operations at hospitals that do a lot of the procedures have better outcomes and less expense. Heart transplant operations, exempt from most insurance coverage because of their experimental status, were approved for coverage by Blue Shield more than a year ago—if they were performed at Stanford. Because Stanford pioneered the procedure, says Dr. Ralph Schaffarzick, senior vice president and medical director of Blue Shield of California, his insurance company could be assured patients were getting the best quality as well as the most efficient care.

BLOOD DONORS WHO MEET A SPECIAL NEED

STANFORD—

Most people who donate blood know it could be used to save a life some day, but Robert Jackson is sure of his donations: Every time he visits the Stanford Medical School Blood Center, he knows he is helping extend the life of a critically ill person.

Strictly speaking, what Jackson is donating isn't a typical unit of blood. He gives blood components—platelets or white cells—through a procedure called apheresis. The blood is taken from one arm, the components separated by means of a centrifuge, the desired component retained and most of his blood is returned through the other arm.

The blood components then go to a hospitalized patient whose blood closely matches Jackson's, and who must have the component transfusions to survive. Most of the recipients need regular transfusions for short periods of time and may be dependent on apheresis donors such as Jackson.

Apheresis is more time-consuming than regular blood donations—it takes about two hours—but it is less draining of the body's resources because few red cells are taken and the components are replenished rapidly by the donor's body. It is possible for an apheresis donor to give blood components with only three days turnaround, compared with eight weeks for regular blood donations.

Most apheresis donors, however, are called on no more than two or three times a year, said Bobbi Ogden, apheresis coordinator at the blood center, "and some may never be called."

Jackson, who is flight director for the Pioneer spacecraft at NASA-Ames Research Center at Moffett Field, is an exception. He has the kind of blood that makes him much sought after for apheresis: It's a common type that matches well with that of many other people.

"Common" in this case doesn't mean type O. The typing used for apheresis donors is human leukocyte antigen (HLA), the same as that for organ transplants. In effect, Jackson's platelets are being transplanted into critically ill patients. And because his blood matches up well with that of the patients, there is less chance of rejection.

The recipients of apheresis donations are usually leukemia patients, ranging in age from infants to people 60 to 70 years old.

"Leukemia knocks out the bone marrow," said Ogden. "They become severely anemic in all blood components. In most cases, they receive blood transfusions from many people. But then they develop antibodies and have transfusion reactions because their bodies are rejecting that blood."

That's where donors such as Jackson come in. When they're called they know there is a crisis—"someone in the hospital is in trouble," Ogden says.

Jackson, a resident of Palo Alto, says he's been called by the blood center about a dozen times so far this year. That probably makes him No. 1 in number of visits, but there are many others in the apheresis program. Ogden says there are about 800, and they're a "very special group."

10-28-86

more-

Stanford wants to increase that donor pool. For one thing, a larger number of donors means greater chances of getting favorable matches for patients in need. In addition, the need seems to be growing; the number of apheresis procedures has been averaging about 100 a month recently, compared with 50-60 a month last year.

There will be an even greater need as Stanford Medical Center proceeds with plans for bone marrow transplantation. It takes several weeks for a transplant to take, and the patients will need transfusions of platelets as well as other blood components to get through the crisis periods.

Almost anyone who can donate blood can become an apheresis donor. "The only criteria are that they be in good health, have good veins in both arms, be 17 to 65 years old and not be taking any anti-inflammatory medicine," Ogden said. "They should weigh 110 pounds minimum and plan on staying in the area a year—it's very expensive to do the typing and we don't want to do it if someone's going to be moving away."

Although most apheresis donations go for leukemia patients, there are other diseases, such as aplastic anemia, that are treated with infusion of platelets.

White blood cells are needed less frequently than platelets, but they're just as important for specific patients. Usually, they are needed by patients on immunosuppressant drugs who develop an infection that doesn't respond to antibiotics.

The procedure is the same for platelets or white blood cells, although it takes 15 minutes to half an hour longer to get the white blood cells. For the donor, it simply means reclining in a chair with needles in each arm. The apheresis machine does the rest.

"It's a little bit uncomfortable to have needles stuck in each arm, but usually it's nothing," Jackson said.

He has never been told the identity of any of the people whose lives he has helped save, and says he has never "pushed" to find out.

What he would like to do, though, is follow some platelets—not necessarily his—through the whole procedure. He's just curious to see how the platelets are handled after they leave his body.

It was similar curiosity that got him involved in the apheresis program in the first place. He was a regular blood donor, saw signs about apheresis and made inquiries.

That was four years and dozens of life-saving donations ago, and the procedure has become routine to Jackson.

It will never become routine, however, to those recipients who would die without his platelets.

ADVISORY TO EDITORS, SCIENCE WRITERS AND MEDICAL WRITERS:

You are invited to attend a scientific symposium at Stanford University Medical School Friday, November 7, focusing on new and upcoming medical applications of cloned gene products. Please alert the Stanford Medical Center News Bureau at (415) 723-6911 if you plan to attend. You may also phone for further information or to obtain a copy of the printed program.

FOR INFORMATION CONTACT: Laura Hofstadter (415) 725-5375 or 723-6911

NEW MEDICAL APPLICATIONS OF CLONED GENE PRODUCTS TO BE FOCUS OF STANFORD SYMPOSIUM

STANFORD—

The newest experimental treatments for conditions ranging from cancer to heart attack will be the focus of the fourth annual symposium of Stanford University Medical School's Program in Molecular and Genetic Medicine, to be held Friday, November 7 in Fairchild Auditorium.

The daylong meeting, entitled "Clinical applications of cloned gene products," will include presentations on treating cancer patients with interferon and tumor necrosis factor, human growth hormone therapy of short children, and new agents that can halt a heart attack in progress.

Other topics will include the potential clinical uses of newly discovered hormones such as interleukin-1, an important immune system agent, and atrial natriuretic factor, a powerful heart hormone.

The symposium features prominent scientists from Stanford Medical School and other institutions.

The speakers, their topics and presentation times are:

- 9 a.m.—Welcome by Stanford biochemistry professor Dr. Paul Berg, director of the Center for Molecular and Genetic Medicine;
- 9:05 a.m.—Introductions to the morning speakers by Dr. Ronald Levy, Stanford associate professor of medicine;
- 9:15 a.m.—"Cachectin: A macrophage monokine that induces a catabolic state and shock," by Dr. Anthony Cerami, professor and head of the laboratory of medical biochemistry at The Rockefeller University;
- 10 a.m.—"Clinical investigation of the interferons and tumor necrosis factor in cancer patients," by Dr. Jordan Gutterman, professor of medicine at the University of Texas System Cancer Center and M.D. Anderson Hospital and Tumor Institute;
- 11:15 a.m.—"Clinical relevance of interleukin-1," by Dr. Charles Dinarello, associate professor of medicine and pediatrics at Tufts University School of Medicine;
- 12 to 1:15 p.m.—lunch break;
- 1:15 p.m.—Introductions to afternoon speakers by Dr. Ronald Levy;
- 1:20 p.m.—"Use of recombinant DNA-derived human growth hormone in the therapy of short stature," by Dr. Ron Rosenfeld, Stanford associate professor of pediatrics;
- 2:05 p.m.—"Coronary thrombolysis with tissue-type plasminogen activator (t-PA): An example of applied molecular biology," by Dr. Burton Sobel, professor of medicine and director of the cardiovascular division at Washington University School of Medicine;
- 3:20 p.m.—"Atrial natriuretic factor: A new class of peptide hormones," by Dr. Ferid Murad, Stanford professor and acting chairman in the department of medicine.

BEST AIDS ANTIDOTES ARE EDUCATION, BEHAVIORAL CHANGE, AND MEDICAL RESEARCH, STANFORD EXPERTS BELIEVE

STANFORD—

During the spring of 1985, eight-year-old Benjamin Oyler began to experience severe bouts of nausea and diarrhea. "At first, we thought it might be an ulcer," recalled his mother, Christine, but their family physician could find nothing amiss.

As Ben's condition worsened, Chris and her husband, Grant, realized "something was really wrong." Their physician advised them to consult the Children's Hospital at Stanford.

Ben, a hemophiliac, turned out to have AIDS, acquired immune deficiency syndrome. His nausea, diarrhea and profound weight loss were due to *Cryptosporidium*, a gastrointestinal parasite that causes just one of the multitude of infections to which AIDS patients are vulnerable.

"We had three hemophiliac sons," Ben's dad recalled recently in an interview at their Carmel home. "We had heard about AIDS . . . but when your own son is sick, you don't think the worst."

Once the diagnosis was made, Ben's parents were faced with the wrenching prospect of watching their son slowly die. "We could feel the doctors mourning along with us. All they could do was treat symptoms. We all knew there wouldn't be a getting better part," Oyler said.

"It is an extraordinarily difficult situation for patients and families, and also for physicians and nurses," admits Dr. Bertil Glader, the Stanford pediatric hematologist who was Ben's physician. "The diagnosis is a condemnation to dying—nobody yet has survived AIDS."

"But when you have a child with AIDS," Oyler explained, "you don't give up hope. You try to outlast the disease to the point where medicine can catch up with it."

But medicine didn't catch up in time to save Ben. He died July 4, 1986, less than a week after his ninth birthday, at home in his parents' arms.

AIDS is presenting medical science with an urgent challenge. "The advent of a new deadly virus was not predictable," points out Stanford pathologist Dr. Edgar Engleman. "We thought we were getting pretty sophisticated in this century—controlling bacterial infections and beginning to come to grips with heart disease and cancer. Suddenly we're faced with a fatal viral infection, and we have to start from scratch."

Medicine is not the only institution challenged by AIDS. The disease is stretching the ethical and moral fabric of society. Extreme, and often irrational, fears about AIDS have surfaced with increasing frequency. Ben was barred from entering third grade at his school because of parents' fears for their children's safety. AIDS patients have lost their jobs, their homes, and have been disowned by their families. Now, proposition 64 on the California November ballot sponsored by the conservative followers of Lyndon LaRouche would even require county and state officials to report and quarantine all AIDS carriers and patients.

Although AIDS is an incurable disease, physicians caution that fear and hysteria are not the solution. The antidote to the mounting epidemic, they say, is biomedical research, education and knowledge that can lead to behavioral change and prevention.

10-23-86 more

AIDS is caused by a virus that destroys cells in the immune system and in the brain, leaving the sick person defenseless against cancers and myriad infections, and susceptible to neurological damage. In many cases, there is a lag time of up to five years or more between the onset of infection and the first signs of disease. Twenty to 30 percent of those infected develop the milder form of disease known as AIDS-related complex (ARC) or full-blown AIDS and its accompanying conditions: *Pneumocystis* pneumonia, *Cytomegalovirus* infection, toxoplasmic encephalitis, tuberculosis, dementia and cancers such as the previously rare malignancy called Kaposi's sarcoma. Due to the protracted lag time, scientists cannot yet say with certainty whether anyone who has been infected will ultimately escape the disease, even though some people seem to remain healthy and symptom-free. Once full-blown AIDS has set in, patients live an average of only three years.

These are sobering facts for people who are infected and admittedly alarming to the population at large. Yet, infected individuals can pass the virus to others in only three ways: through intimate heterosexual or homosexual relations, exchange of blood or from an infected mother to her fetus.

It is essential for people to understand that safe sex, such as reducing the number of sexual partners and using condoms to avoid exchange of body fluids, could go a long way toward curbing the spread of AIDS, says immunologist Dr. Dennis McShane. Eliminating intravenous drug use—or at the very least avoiding sharing needles and other drug apparatus—is also critical.

"The risk for becoming infected with the AIDS virus does not have to do with being a homosexual man or being a member of any group," explains Dr. Anthony Fauci of the National Institute of Allergy and Infectious Disease in a recent Science article. "The risk for AIDS is a behavior—having sex with someone who is infected or being exposed to blood that is infected."

Because important facts about its transmission are not fully understood or appreciated by the public, AIDS is gradually spreading from the "high risk" groups—male homosexuals and intravenous drug users—into the general population. Although the medical consensus is that there's no need for hysteria, there is also a growing realization that curbing AIDS' incidence may not be possible unless preventive measures become everyone's concern.

"There is no indication that AIDS will diminish soon," says Glader. "It's been projected that in 1991, more people will die of AIDS than will die from automobile accidents."

Federal statistics present a glimpse of the future burden of the disease. Since 1981, when AIDS was recognized in the United States, nearly 35,000 people have been diagnosed; by the end of this year, 18,000 of them will have died. In 1986 alone approximately 16,000 cases will have appeared, and 9,000 people will die. By 1991—only five years away—more than one-quarter of a million new cases of AIDS are expected—3,000 of them children—and a total of 179,000 people will have died. Fifty-four thousand deaths are expected in 1991 alone, approaching the number of U.S. casualties during the entire Vietnam war.

In Africa, where it is believed to have first infected heterosexuals, the AIDS virus may lurk in up to two percent of the population. In the United States, 1 to 1.5 million people are thought to be infected, with as many as 1,000 new exposures occurring every day. The medical costs in 1991 for AIDS are projected to be anywhere from $8 to $16 billion.

Although scientists have made headway against the disease, behavioral prevention of AIDS remains the only course until the remaining obstacles to finding a vaccine and a treatment can be overcome.

AIDS research passed a first milestone in 1984 when scientists in the United States and France identified the AIDS virus. A second goal was reached after scientists learned that the virus was passed through blood and that high temperatures could kill it. That enabled them to institute heat treatments for the blood components given to hemophiliacs. Another major step came in 1985 when the nation's blood banking industry adopted an effective screening test to identify infected blood and prevent AIDS spread by blood transfusion. Stanford's own blood center had pioneered almost two years earlier when it became the nation's first blood bank to screen for potentially infected blood.

more-

"For the time being, the blood supply is much, much safer," asserts Engleman, Stanford blood center's medical director. But since there will never be a perfect screening test—an estimated 120 units of tainted blood may slip by each year with the current one—there will probably continue to be a few cases of transfusion-mediated AIDS, he says.

More contaminated blood could enter the blood bank system as the number of cases in heterosexuals continues to rise, Engleman cautions. "Right now, it isn't just the screening test that's slowing the spread" he explains. "It's the fact that people in the high-risk populations have made a conscientious effort to stop donating blood." But as the disease spreads to "low-risk" individuals who don't suspect they are carriers, the problem could grow again.

Engleman's lab and others are working on more sensitive tests that may become commercially available to blood banks within the next two years. More pressing, he explains, is the need to learn more about the AIDS virus and the biology of the disease.

He and associates Jeffrey Lifson, Michael McGrath and Barry Stein want to know how the virus causes damage. The AIDS virus, they have found, latches onto a specific protein found on helper-T lymphocytes and monocyte macrophages, cells that play a vital role in orchestrating the body's immune defenses. Once the virus latches onto the protein "hook," it then slips inside and commandeers the cell machinery to manufacture more virus particles. To make matters worse, a cell hijacked by the AIDS virus can act like a sponge, sopping up many of its uninfected counterparts to form giant cell conglomerates. These giant cells ultimately die, depleting the immune system of the very cells it needs to defend against disease. This makes the patient vulnerable to the slightest infection.

The ultimate measure against AIDS would be a vaccine. Several Stanford scientists are working toward this goal. Virologist Dr. William Robinson and colleagues are attempting to design a "synthetic-peptide" vaccine. It would consist of a small piece of laboratory-manufactured protein that would mimic the protein coat of an AIDS virus particle. When injected, it would trigger the person's immune defenses to a state of readiness to fight off the actual virus.

The biggest challenge in designing an AIDS vaccine is to make sure it protects against different strains of the virus. David Ludwig, a medical student, and medical microbiologist Dr. Gary Schoolnik are testing an approach that could accomplish this. Their vaccine, based on "anti-idiotype" methods, would interfere with the virus' ability to bind to the protein hooks it uses to invade cells. Since all strains of the virus are thought to invade cells by means of this protein, the vaccine could prevent infection by a variety of differing strains.

However, vaccine researchers are only cautiously optimistic right now. They know that the AIDS virus may be closely related to animal lentiviruses, microbes that can incubate in the brain for decades and against which no effective vaccine has yet been devised. Even if scientists can surmount the obstacles, any vaccine against AIDS is still more than five years away, due to the extensive testing that would have to precede its widespread use in people, explains Dr. Thomas Merigan, head of infectious diseases at Stanford. And once it's ready, getting it to all who need protection will be a monumental task.

Then, what about people who are already infected? To combat ongoing disease, a vaccine is useless. Effective drugs must be found. In June, the National Institute of Allergy and Infectious Diseases announced a five-year $100-million program to test drugs that have shown potential to fight AIDS. Stanford medical school, in collaboration with the Kaiser Hospital in San Francisco, is one of 14 institutions involved in the national study, which may enroll as many as 1,000 patients. Led by Merigan, Stanford and Kaiser physicians will oversee trials of drugs that may inhibit growth of the AIDS virus. Other institutions will examine drugs that may control the infections and malignancies prevalent in AIDS patients.

Many of the drugs to be tested in the first year of the study act by inhibiting a crucial enzyme—reverse transcriptase—that the AIDS virus uses to reproduce itself. Others may bolster and strengthen the AIDS-debilitated immune system. Most physicians are skeptical that any single agent will suffice, Merigan says. One hurdle is the blood-brain barrier—any drug against AIDS will have to be able to get past it in order to reach infected cells in the brain that could otherwise stay sequestered, yet continue to cause damage for years.

Also daunting is the knowledge that the AIDS virus is a retrovirus, a class of viruses that has so far defied drug control. There probably won't ever be a cure for AIDS, Merigan admits, only treatments to suppress symptoms. Even that poses challenges. "In other diseases such as hepatitis, we have found drugs that can terminate an acute episode. But if you stop therapy, you get a recurrence. The same could very well be true for AIDS," he says.

more

The drug strategy that will eventually subdue AIDS, he adds, will depend on interweaving antiviral medications and immune boosters. Ideally, researchers would like to have a drug that suppresses the virus in infected people who have not yet developed disease even though such a drug would have to be taken for the rest of the person's life to continuously muffle the virus.

As if an AIDS vaccine and treatment strategy weren't enough of a challenge, that isn't all that's needed. Scientists also must seek drugs to treat the different infections and malignancies that make AIDS so devastating. Merigan's lab is exploring new drug treatments against *Cytomegalovirus* infection, one prevalent disease associated with AIDS. Stanford oncologist Dr. Sandra Horning leads a study of lymphatic system cancers—Kaposi's sarcoma and lymphomas—in patients with AIDS.

Dr. Jack Remington, infectious disease specialist at Stanford and the Palo Alto Medical Research Foundation, is pursuing new approaches to one of the more deadly AIDS-associated illnesses, toxoplasmosis, a parasitic infection that can affect the brain. Most people are infected with *Toxoplasma* organisms but never become sick because a healthy immune system keeps the parasite quiescent. "But AIDS ticks off these little bombshells" in up to 10 percent of AIDS patients, he explains. Without treatment, it leads to death within months.

Remington is searching for diagnostic methods to replace brain biopsy, the radically invasive procedure often needed to confirm *Toxoplasma* encephalitis. New drugs he's exploring against toxoplasmosis may possibly replace the effective but sometimes toxic medications currently available. His lab is also studying "biologicals," immune system-bolstering agents that in animal studies have been shown to provide protection against *Toxoplasma* encephalitis.

New work by government scientists suggests that it may take more than the AIDS virus alone to cause the disease—another newly discovered virus may play a role. That there may be an intimate association between AIDS and other diseases has intrigued scientists all along. Remington, for example, is studying a possible link between the *Toxoplasma* organism and the AIDS virus. They are found in the same parts of the brain in AIDS patients, suggesting that they may influence each other in some cause-and-effect way.

Robinson is looking at interactions between the AIDS virus and other organisms, trying to learn why one patient infected with the AIDS virus becomes sick right away while another lives in good health for years. There is circumstantial evidence that people who have several concurrent infections—as is true for many gay men—may develop AIDS more readily than others, Robinson says. His lab team is trying to determine whether the viruses that cause these other infections help stimulate a latent AIDS virus into activity.

As researchers around the country are beginning to translate laboratory findings into clinical use, they face a whole range of troubling ethical issues, however. One question is how to test accurately the efficacy and safety of potential AIDS drugs without temporarily withholding potentially lifesaving treatment. Some researchers have suggested that the traditional method of drug testing—in which half the patient volunteers in a study receive an inert substance instead of the test drug—should be thrown aside in evaluating drugs for a uniformly lethal disease such as AIDS. All patients who want experimental drugs should be able to get them, contends Dr. Mathilde Krim, a Columbia University scientist.

But the investigators in Stanford's AIDS treatment evaluation unit believe that imperfectly controlled studies don't give reliable information and that introducing unproven experimental drugs, even on a "compassionate use" basis, could actually do desperate patients more harm than good. Even if it means denying drugs for now to some patients, "The most important thing is to get the *right* answer as quickly as possible" to provide the greatest benefit, Robinson says.

McShane, who sees many AIDS patients in his practice, raises an equally thorny problem. Now that a screening test for infection by the AIDS virus is available, there is pressure from the frightened public to mass-screen individuals in the high-risk groups, he explains. The Centers for Disease Control have recommended that all gay men be tested. Not only would the individual learn about his health status, screening proponents argue, but sexual contacts could then be traced and informed of their risk.

But McShane argues against mass screening in the high-risk groups since there is no treatment available for those who test positive and the test cannot predict who will get sick among those infected. Furthermore, he says, high-risk individuals should follow preventive guidelines, no matter how the test turns out.

"Whether the person is positive or negative the bottom line is the same," he explains. "If the person's positive, he doesn't want to transmit the disease, so he should follow safe sex practices, like limiting the number of partners and using condoms.

"But if the test is negative," McShane continues, "he wants to make sure he doesn't get the disease. So, the precautions are exactly the same: use safe sex practices, forgo IV drug use, and so forth."

The test can be useful in specific cases, he adds, such as for advising a positive hemophiliac or bisexual man not to father children.

But many experts remain reluctant to use the test on a widespread scale because of concerns about constitutional issues such as individual rights and liberties, should the information be misused. Some states, such as Colorado, require mandatory reporting. The results could be used in a discriminatory fashion by insurance companies or employers, McShane argues.

"We have not done testing on many of our hemophiliac patients because from statistical data, we know the likelihood of whether or not they are infected," Glader notes. "And because of the political aspects, you're almost better off not knowing."

Widespread testing would lay the groundwork for medically unsound measures such as the quarantine implied in the LaRouche initiative, McShane says. Most doctors and medical groups, including the California Medical Association, have denounced that measure, he points out.

Prevention can only be accomplished when individuals are well informed, McShane suggests. And, echoing a recent editorial in the *New York Times*, he bemoans the "feeble fight" the federal government has so far mounted against AIDS. "Not nearly enough education has been done except at a grass roots level," he contends. "We must stress over and over again that this is not a disease that can be transmitted through casual contact. But the disease's spread can be slowed or eliminated only if people understand that it's their own decision—the disease is acquired through behavior the individual can control."

At least for now, once individuals become infected they have relatively little control over the course of their disease. However, a study of AIDS patients at San Francisco General Hospital suggests that patients are making decisions about their medical care, says Dr. Thomas Raffin, codirector of Stanford hospital's intensive care units and chairman of the medical center's ethics committee.

The study found a changing pattern of intensive care unit admissions among AIDS patients with the highly lethal *Pneumocystis* pneumonia. As the number of AIDS patients diagnosed with this condition rose, the number of patients admitted to the intensive care unit dropped, the opposite of what would be expected if the most aggressive treatments were pursued. The explanation appears to be that AIDS patients with only a slim chance of survival are deciding early on in the course of their disease not to be placed on intensive care life support should the choice arise.

And all evidence suggests that at least for the next few years, that agonizing choice will come up more frequently as the AIDS epidemic grows. Researchers are the first to admit they don't have the desperately needed answers yet, but they nevertheless are confident that biomedical science has the tools to proceed. Says Engleman: "It's a close race, but I believe we will control this disease with time."

GENE STUDY MAY PROVIDE A CLUE TO HOW AIDS VIRUS INFECTS THE BRAIN

STANFORD—

A new finding about how the AIDS virus may infect brain cells has been reported by Stanford University Medical School scientists.

The finding, to be published in the October 31 issue of *Science*, centers on a gene which plays a critical role in regulating immune reactions in mice and humans.

This gene is active in the white blood cells that the AIDS virus infects, where it controls a molecular "lock" through which the AIDS virus enters the cells.

The new findings have revealed for the first time that this same gene is also active in brain tissue, suggesting that the AIDS virus gains access to cells in the brain through the same lock that enables it to penetrate the immune system.

Although the experiments were carried out in tissues from mice, the researchers believe the results are highly likely to carry over into humans because of extraordinary similarities in the roles of this particular gene and a closely related one in humans.

But the scientists were careful to point out that further research is needed to prove that the human gene is active in brain tissue and that its activity underlies AIDS infection in the central nervous system.

The researchers were able to determine that the gene is active in mouse brain tissue as a result of another feat which they reported in the same paper: the determination of the gene's structure.

Because the gene plays a central regulatory role in the immune response, the Stanford team's work should lead to new insights about how the immune system recognizes foreign materials in the body, as well as providing information on how the AIDS virus could be invading cells in the nervous system, said Dr. Jane Parnes, Stanford assistant professor of medicine who led the study.

Parnes noted, however, that it is too early to know whether these new findings might be useful in developing a treatment strategy against AIDS. "That is far downstream," she said.

The research was carried out in Parnes' laboratory by postdoctoral fellows Drs. Beatrice Tourvieille, Scott Gorman, and Elizabeth Field. Tim Hunkapiller, a graduate student at the California Institute of Technology, was also a collaborator.

Although researchers have known for some time that the AIDS virus can infect the central nervous system, causing a variety of severe neurological symptoms in patients, they haven't known what kinds of brain cells it infects nor how it gets into them.

The new study provides a clue to how the AIDS virus gets into cells in the brain, although it does not answer the question of which kinds of brain cells are susceptible to infection by the virus. Further studies may reveal the answer to that question, Parnes said.

10-22-86 more-

Additional research has already suggested that the gene is active in certain support cells in the brain known as astrocytes, she added.

Scientists also have known for some time that the human equivalent of the newly deciphered gene was implicated in AIDS. The human gene controls a protein, called CD4, found on the white blood cells in the immune system that the virus infects—the T helper cells.

By binding to the CD4 receptor protein the AIDS virus unlocks and infects the cell.

The CD4 protein is known to be much more than a lock, however. Over the years, researchers have realized that it plays a critical role in triggering the body's immune response. Although its exact function isn't known, it is thought to help T helper cells recognize foreign cells.

Scientists at Columbia University recently made an important advance when they isolated the CD4 gene in humans, Parnes said. However, because it can be very difficult to study human tissues and processes, she and her colleagues pursued the analogous "L3T4" gene in mice.

Parnes explained that although the L3T4 protein in mice plays a very similar role to that of CD4 in humans, their new study has revealed some structural differences between the proteins from the two species that could help explain why L3T4 is not a receptor for the AIDS virus, and thus why mice don't get AIDS.

In the *Science* article, the researchers also reported on experiments which showed that the L3T4 gene seems to be active in brain tissue in two different ways, in contrast to its single form of activity in the immune system.

Parnes and her colleagues would like to find out what role this gene plays in the brain. The new work adds one more intriguing bit of information to scientists' growing knowledge about a family of structurally similar genes that are active both in the immune system and in the central nervous system, Parnes said.

The research was funded by grants from the National Institutes of Health. Fellowship support was provided from three French agencies (the Ministere des Affaires Etrangeres-France, the Ligue Nationale Francaise contre le Cancer, and the Philippe Fundation) and from the National Cancer Institute, the Bank of America-Giannini Foundation, and a John A. and George L. Hartford faculty award.

STANFORD REORGANIZES RADIOLOGY DEPARTMENT

STANFORD—

Stanford University School of Medicine's department of radiology has been split into two discrete academic units — the Department of Therapeutic Radiology and the Department of Diagnostic Radiology and Nuclear Medicine.

The change became effective Sept. 1.

Dr. Ronald Castellino, professor of radiology, has been named acting chairman of the Department of Diagnostic Radiology and Nuclear Medicine. Dr. Malcolm Bagshaw, Catharine and Howard Avery professor and chairman of radiology since 1972, will continue to lead the Department of Therapeutic Radiology which includes the Divisions of Radiation Therapy and of Radiation Biology.

"Conceptually, the two disciplines are different and there has been a desire for a long time that they be separated," said Vice President and Dean David Korn. "Changes in specialty training and board certification, the increasing complexities of medical practice, and marked national trends all support this decision."

Until the 1960s, most persons trained in radiology and nuclear medicine had clinical training in the three disciplines — diagnostic radiology, nuclear medicine, and radiation therapy. Since then, there has been increasing emphasis here and nationally on separate training and certification. Most of Stanford's current faculty in each of the three clinical divisions have been trained in only one of these specialties.

Radiation is used for its biological effects, particularly but not exclusively in the treatment of cancer. Physicians in the field of diagnostic radiology and nuclear medicine use radiation primarily for diagnosis.

Castellino, who joined the Stanford faculty in 1968, has served as director of the diagnostic division since 1981 as well as associate chairman of the department of radiology. Prior to that he headed the diagnostic oncologic radiology section, the first such subspecialty section at a major medical center, and also directed the computerized tomography (CT) body scanning program.

He is noted for research leading to improved techniques for evaluating patients with cancer, especially spread of cancer to lymph nodes throughout the body, using radiographic techniques of lymphography and CT body scanning.

Born in New York, Castellino grew up in Brazil. He received the M.D. in 1962 from Creighton University School of Medicine in Nebraska. He completed his residency training in diagnostic radiology at Stanford in 1968 prior to joining the faculty.

Korn indicated that consistent with the school's policies, he will seek a full outside review of the new Department of Diagnostic Radiology and Nuclear Medicine in the near future. Reviews cover departmental structure, resources, academic goals and leadership.

PSYCHOLOGICAL TECHNIQUES TESTED TO CONTROL CANCER PAIN

STANFORD—

Cancer patients can adopt easily-learned psychological techniques to help them control pain and stress, according to preliminary results of a Stanford Cancer Pain Management study.

Dr. David Spiegel, associate professor of psychiatry and director of the study, said this week that many patients report that pain control techniques such as hypnosis and biofeedback help them feel less victimized by their pain and more in control of their illness.

"Ironically, techniques like hypnosis are too often associated with **loss** of control. Actually, patients who learn to hypnotize themselves at the exact time that they need it feel much **more** control over their pain and their lives," said Spiegel.

The need to provide means of reducing the pain of cancer is clear, Spiegel said. Earlier studies have shown that between 60 and 80 percent of patients whose cancer has spread from its initial point suffer substantial pain. But Spiegel added that comparatively little research has been done on how to relieve pain.

About 140 more volunteers are needed now at the midpoint of Spiegel's two-year study to join some 60 persons who have already been accepted. Potential volunteers must have received a diagnosis of cancer—of any type and at any stage. Those with high levels of pain will be compared with those who are feeling little if any pain.

"Cancer patients can experience a tremendous sense of mastery when they focus on symptoms that are treatable—such as their pain, their depression and their anxiety," Spiegel said.

As predicted, the researchers are finding significant levels of depression and anxiety among the current group of cancer patient volunteers who are reporting pain.

But the scientists are also finding how patients can take specific action to conquer or at least control their pain.

For example, one patient reported being able to reduce her anxiety while going through chemotherapy in October by using self hypnosis to visualize herself horseback riding.

Another patient, while in a trance state, pictured a garden hose cooling the painful area in her back, and she later described how satisfying it had been to "play with" her pain.

Spiegel reported his most recent patient findings earlier this month at the American Cancer Society's Feature Writer's Forum in New York City. Spiegel said this was the first conference of its kind, an indication of the growing interest by both patients and physicians in the psychosocial aspects of cancer treatment.

In the current study, all volunteers will receive at no cost to themselves a complete psychological evaluation.

Dr. Susan H. Sands, research psychologist, said half the volunteers will receive specific treatment for pain, including self-hypnosis and biofeedback techniques, as well as more traditional treatments such as antidepressants, antianxiety medications and individual psychotherapy.

The researchers will compare measures of pain, mood disturbance and social support among the treatment and control patients at intervals of one, three, and six months.

For further information or to volunteer, contact Sands at (415) 723-6341. Sands said volunteers might be asked to make several trips to Stanford Medical Center, although patients requiring bedside or home visits by researchers can be accomodated.

MAGNETIC RESONANCE IMAGING SHEDS NEW LIGHT ON KNEE INJURIES

STANFORD—

The powerful imaging capability of magnetic resonance may lead to its playing an increasingly important role in the diagnosis and treatment of common knee injuries, according to a Stanford University Medical Center scientist.

The revolutionary imaging method reveals so much about menisci, the cartilage in the knee joint, that Dr. John Drace, Stanford medical school assistant professor of radiology, has developed a new classification system describing different types of injuries, including some that could not be seen before.

Drace, also a radiologist at the Palo Alto Veterans Administration Medical Center, is conducting clinical trials to support his classifications and the effectiveness of magnetic resonance imaging (MRI) for diagnosing knee problems involving the menisci.

"So far, the classification system is dramatically improving the sensitivity and the specificity of diagnosing knee injuries with MRI," Drace said.

The menisci are triangular-shaped cartilage wedges positioned between the tibia and femur on either side of the knee. They serve as a cushion, preventing the bones from grinding against each other and absorbing the impact of physical activity. Many active or athletic people stress the knees to the point that the cartilage is damaged or torn, causing extreme pain.

Until now, physicians have only been able to diagnose definite tears that affected the surface of the cartilage, Drace explained. MRI, however, allows them to "see" within the cartilage to detect internal tears as well as other weak spots or disease.

Formerly corrected only through major knee surgery, meniscal injuries in recent years have been fixed with arthroscopic surgery. With arthroscopy, physicians need only make a few small incisions in the knee area. Then, guided with a special scope, they can make the necessary repairs with tiny surgical tools. The procedure is often done on an outpatient basis with much less inconvenience and a much shorter recovery period for patients.

Yet even with the great improvement of arthroscopic surgery, Drace said, physicians still have been limited in their diagnostic capabilities. A painful and invasive procedure called an arthrogram, in which a contrast dye is injected into the patient's knee, is increasingly bypassed because in very few instances do physicians find it useful. Most physicians make an initial diagnosis during a physical examination of the knee, and then confirm the diagnosis and correct the problems during arthroscopic surgery.

With MRI however, possible unknowns are eliminated, Drace said. It allows physicians to see the menisci from any angle, revealing problems that otherwise may remain covered up. It is noninvasive, and it takes about an hour to complete.

The technique is based on the nuclear magnetic resonance phenomenon discovered by the late Stanford physicist, Felix Bloch, and Edward Purcell of Harvard. Patients are placed in a powerful magnetic field capable of rapidly aligning the nuclei of the body's atoms, which possess a property known as spin. Each molecule has such proton atoms. Radio waves beamed at patients "tilt" the nuclei, which then emit signals that can be used to form images of internal body structures such as the menisci.

"When there's a complete tear it's no problem to diagnose," Drace said. "The problem comes up when there's some type of degenerative or subtle change that's harder to diagnose. But you can see it with MRI. MRI shows you 'sick' menisci, not just torn menisci."

Drace said MRI is not really competing with arthrography since many physicians rarely use the diagnostic technique anyway. "We're not really competing with arthroscopy either, although we may save a few people from having them," he added.

COCAINE CAN DAMAGE THE HEART, STANFORD MEDICAL SCHOOL STUDY CONCLUDES

STANFORD—

Cocaine can cause life-threatening damage to heart muscle tissue, according to a report soon to be published by researchers at Stanford University School of Medicine and the San Francisco Medical Examiner's Office.

It is apparently the first study to find a specific anatomical lesion in the heart muscles of a group of cocaine users, although another recent medical report documented a similar finding in a single patient, said Dr. Henry Tazelaar, the Stanford surgical pathologist who coordinated the study.

Cocaine, which has been known for its euphoric and stimulatory effects in South America for thousands of years, has experienced a recent surge in popularity in the United States which may, in part, be due to the perception that it is a relatively safe drug.

Only in the past year have medical researchers become aware that cocaine can have direct, destructive effects on human heart tissue, Tazelaar said. Angina, heart attack, coronary artery spasm, irregular heart rhythms and sudden death all have been associated with cocaine use.

"The evidence is mounting up that cocaine is not the benign drug it was once thought to be," Tazelaar said in a recent interview.

The heart damage caused by the drug is of a type that can trigger irregular heartbeat patterns which, in some cases, can lead to sudden death, he said.

"Although some people may be more susceptible than others to these effects of cocaine on the heart," he added, "the bottom line seems to be 'don't fool with cocaine'."

The findings are "provocative and potentially clinically important," the researchers wrote in their report, which has been accepted for publication in an upcoming issue of the journal *Human Pathology*.

Tazelaar's coauthors on the study are Dr. Steven Karch, visiting scholar at Stanford, Dr. Boyd Stephens, chief medical examiner in the San Francisco Medical Examiner's Office, and Dr. Margaret Billingham, Stanford associate professor of pathology.

Karch presented the study's results at a meeting of the University Association for Emergency Medicine in Portland, Oregon earlier this year.

The research was supported by a grant from the National Heart, Lung and Blood Institute.

The researchers examined tissue samples from the hearts of 30 people, aged 25-74, determined by the San Francisco Medical Examiner's Office to have died of cocaine toxicity.

They also examined heart tissues from 20 other drug overdose victims who had not used cocaine, as controls for comparison.

In 28 out of 30 of the cocaine users, microscopic study revealed that the heart tissues contained red streaks known as "myocardial contraction bands." Only nine of the control hearts displayed similar lesions, and they had fewer of them, the report said.

These bands arise when muscle cells enter a permanent state of contraction that immobilizes them, Tazelaar explained.

more

"Once it's happened, the cells are essentially useless," he said. "It's an irreversible process. And because you get these useless, or dead, cells sitting in the way, the normal conduction pathways of the heart don't work like they should," he added.

With the normal conduction pathways blocked, the heart is much more likely to beat in irregular patterns called arrhythmias. Severe arrhythmias can cause sudden death, Tazelaar noted.

Such bands have been identified in more than 80 percent of patients dying of sudden cardiac death unassociated with cocaine use, he noted.

"This new information may help to explain the cardiac arrhythmias and sudden deaths that are associated with cocaine use in the absence of coronary disease," Tazelaar suggested.

Contraction bands can be caused in a variety of ways, Tazelaar said, and are already known to be associated with the substance norepinephrine.

In a complex series of chemical steps, Tazelaar explained, an increase in norepinephrine may disrupt calcium metabolism, leading muscle cells to enter a state of permanent contraction, or hypercontraction. "It's almost as though the chemical apparatus involved in contraction gets jammed," he said.

"Attempts to revive or resuscitate patients are known to induce hypercontraction and contraction bands," Tazelaar explained, because drugs like epinephrine and norepinephrine may be given during resuscitation efforts.

Since resuscitation attempts had been made in approximately half of the drug overdose cases, the contraction bands seen in the study could have arisen in several ways, Tazelaar acknowledged,

"But even taking that into account, there were a lot more contraction bands in the cocaine users than in the non-cocaine users," he said.

Although the scientists do not yet have proof, they suspect that people who don't have any problems initially may be damaging their hearts over time, and be unaware that something is happening.

"We are particularly concerned about this in young people, because later in life when they begin to get regular coronary artery disease, it may be that the already damaged heart will be that much less able to withstand the added stress of another disease process," he noted.

"It is possible that young people who are now using cocaine may be setting themselves up for problems 20 years down the road," he cautioned.

One practical outcome of the study is that contraction bands may help coroners make a diagnosis at autopsy in suspected cases of lethal cocaine overdose, as they have in cases of sudden death associated with usual atherosclerotic coronary disease, Tazelaar noted.

"Contraction bands may provide confirmatory evidence at autopsy that cocaine toxicity was the cause of death," he explained. "They might suggest cocaine as the culprit for sudden or unexpected death if no other cause for contraction bands is identified, and if a blood or urine drug screen shows the presence of cocaine."

Tazelaar noted that in the past year or so, "there have been reports of 15 or more documented serious cardiac events in people who have used cocaine."

"I think these findings may provide insight into the deaths of the seemingly fit young athletes we've all heard about," he said, "although we haven't examined any of their heart tissues."

CONFERENCE TO HELP "SANDWICH GENERATION" COPE WITH DOUBLE RESPONSIBILITIES

STANFORD—

A conference on "The Sandwich Generation"— adults concerned about caring for aging parents and at the same time possibly trying to raise a family of their own — will be held Nov. 8 at the Lucie Stern Community Center in Palo Alto.

The conference is sponsored jointly by the Stanford University Hospital Home Health Care Services and the Palo Alto Area Information and Referral Services (PAAIRS).

It will feature addresses by Dr. Carol H. Winograd, assistant professor of medicine at the Stanford School of Medicine; Kathleen McConnell, director of health and social services for the Senior Coordinating Council of Palo Alto; and Dr. Thomas A. Raffin, associate professor of medicine at Stanford and assistant chief of medicine at Stanford Hospital.

Winograd, who is also clinical director of the Geriatric Research, Education and Clinical Center at the Palo Alto Veterans Administration Medical Center, will disuss "The Aging Process"; McConnell will speak on "Emotional Issues for Caregsivers"; and Raffin will discuss "Withdrawing Life Support: A Medical/ethical Issue."

In addition, there will be three workshops: Drew Bradley, president of The Hillsdale Group, will lead one on "Group Living Arrangements"; Barbara Burgess, clinical nursing coordinator of Stanford's Home Health Care, will host "Care at Home"; and Susan Tilton, program manager of the department of community services at Little House in Menlo Park, will be the leader for "Support for Seniors in Group Settings."

Lori Anderson, director of planning for the Council on Aging of Santa Clara County, will deliver an opening address, "The Challenge is Ours." Kathryn Janz, director of Stanford's Home Health Care Services, will be the program moderator. Dorothy Low, vice president of the Senior Coordinating Council of Palo Alto will give a welcoming speech.

The conference will run from 8:45 a.m. to 1 p.m. There is a registration fee of $5.

Further information may be obtained by calling (415) 723-8395.

$19.6 MILLION MEDICAL SCHOOL CONSTRUCTION PROJECTS APPROVED

STANFORD—

Two Stanford University School of Medicine construction projects totalling $19.6 million have been approved by the University Board of Trustees.

The projects comprise the second construction phase of the animal research facility, and renovation of portions of the second and third floors of the Boswell Building which houses the Stanford University Clinic.

The trustees have authorized a budget of $16.9 million for the second phase of the animal facility construction. The project will be funded by long-term debt, according to the trustees' action.

The project will add about 44,000 gross square feet as a single story underground facility located immediately south of the Center for Molecular and Genetic Medicine site now under excavation. The project, designed by the San Francisco architectural firm of Stone, Marraccini and Patterson, will bring animal facilities to full code compliance and allow consolidation of animal facilities now scattered at several campus locations, the trustees said.

Construction of the new facility is estimated to start in April 1987, with completion expected in late summer of 1988.

The completed first phase of a state-of-the art animal facility serves only about 50 percent of the institution's research animal needs. The rest, mostly mice and rats, are housed in various satellite facilities throughout the Medical Center.

The budget approved for the renovation of the Boswell Building will be $2.7 million. The project covering the renovation of some 12,000 gross square feet will continue the upgrading of the Boswell Building, according to the trustees action.

Costs will be funded by gifts from the James G. Boswell Foundation of Los Angeles, which supported an earlier major renovation of the Clinic. Most of Stanford's 90 specialty and subspecialty outpatient clinics are in the Boswell Building. The Stanford University Clinic is the medical practice base of some 280 faculty physicians. It averages more than 144,000 outpatient visits per year and is a major local and regional resource of patient care.

The renovated space will accomodate several clinic areas, including Gynecology and Obstetrics, Cardiology, Neurology, Primare Care, Cardiovascular Transplantation, the Stanford Medical Group and clinic administrative offices.

As in the earlier renovation of the Boswell Building, the new design by the architectural firm of Almeter and Finley of Palo will provide "an improved functional environment for staff and physicians while providing a relaxed, comfortable atmosphere for patients.

Project construction will be started in summer of 1987 and will be completed in October, 1988. It will be phased over a 16-month period so as to minimize inconvenience to patients and clinic physicians.

NEW SIDS RESEARCH TO FOCUS ON INFANTS' NERVOUS SYSTEMS

STANFORD—

A Stanford University Medical Center researcher trying to solve the mystery of Sudden Infant Death Syndrome (SIDS) thinks the answer may be found in the largely overlooked area of the development of infants' central nervous systems.

Thus far, says Dr. Ronald Ariagno, associate professor of pediatrics, most of the research on SIDS has focused on cardiovascular and respiratory systems. He intends to explore circadian (day-night) rhythms, thermoregulatory control and similar functions controlled by the nervous system—and in particular, changes in their interaction with development.

SIDS is the number one cause of death in children between one month and one year, killing between 7,000 and 10,000 infants in the United States each year. The deaths are sudden and unexpected and the causes are undetected by autopsies.

Pending funding sources for Ariagno's research include the National Center for the Prevention of SIDS and the National Institutes of Health. He will receive money for pilot projects to start the most current research from an elaborate SIDS benefit being organized to support his studies.

The benefit is being planned by Gretchen Cebrian, a San Francisco public relations executive who lost a six-month-old son to SIDS last March. She expects 300-400 persons to attend the $200-a-person, black tie dinner-dance at the Fairmont Hotel on Nov. 6.

Besides providing initial funding for Ariagno's project, the benefit is intended to call attention to the problem of SIDS. Cebrian notes that President Reagan has declared October "National Sudden Infant Death Syndrome Awareness Month."

Ariagno has been conducting SIDS research at Stanford for 10 years. He said there is a general belief among researchers that a large percentage of SIDS cases result from apnea, "the interruption of the normal breathing rhythm long enough to cause changes in oxygen and slowing of the heart rate."

He added, "The primary causes of apnea and the factors which modulate respiratory control in the neonate are what really need to be examined in greater detail." He said his research will attempt to discover if "the mechanisms for SIDS are in the nervous system, and especially the brain stem ... as it relates to the control of breathing, temperature regulation, circadian rhythmicity and arousal state control."

Studies at Stanford of babies with apnea produced a significant amount of information about infants with nptomatic apnea, Ariagno said, but "we didn't find a pathological marker" that would identify which babies (symptomatic or asymptomatic) were at greatest risk for SIDS.

2-2-2

"We know there's some problem with breathing," he said, "some problem with perhaps regulation of temperature, that it occurs during sleep, and primarily at night or early morning. ... What we'd like to do is to consider all of these factors and to examine the importance of the day-night (circadian) organization of the nervous system."

Ariagno plans to study approximately 50 babies a year for a five-year period. Some will be full-term babies, but he plans to concentrate on premature infants, not only because their nervous systems are less mature and may reveal more about how the systems develop, but also because preterm infants are at significantly greater risk for SIDS.

"In a nervous system from a baby of 28 weeks' gestation (three months early)," he said, "environmental cues from the mother are withdrawn; they're not there. The baby is essentially in an artifical environment which may be non-optimal for the developing nervous system."

Steve Glotzbach, a sleep researcher and physiologist who will collaborate with Ariagno on the studies, pointed out that the environmental adjustment is compounded for infants in neonatal intensive care units who may have their circadian rhythms disturbed by the constant light of the nurseries.

He emphasized the need to examine the relationships of circadian rhythms with other physiological factors. "We know that the thermoregulatory system is severely inhibited during REM (rapid eye movement) sleep," he said, "and that thermal stimuli have important influences on respiratory and arousal state control.

"Since constant light has been shown to disrupt the normal coupling of different physiological systems in animal studies, we need to examine the effect of different photoperiodic environments on the physiology of the neonate."

"From looking at what happens to the nervous system from 28 weeks to term," Ariagno said, "we hope to learn what developmental achievements are present, when those achievements aren't there what significance they have to the baby's ability to respond, and their importance in understanding the potential lethal vulnerability of that infant."

The "lethal vulnerability" Ariagno referred to comes from an analysis of the risk for SIDS among premature infants born at Stanford over the past 20 years. Those born early enough to weigh less than 1,500 grams (3.3 pounds) at birth were in the highest risk category for SIDS. The incidence of SIDS in that group, he said, was 1 to 2 percent, about 10 times as high as the 1 to 2 deaths per thousand in the general population.

It will not be possible to do all of the planned studies on an individual infant. Therefore, a group of infants will be required. The studies are designed to analyze the interaction of thermoregulatory control, respiratory control, sleep organization, arousal control and the development of sleep-wake organization.

"Our focus is going to be on what effects these factors have on the development of the nervous system and on the basic physiological responses which are necessary to protect the individual and decrease vulnerability to a lethal problem," Ariagno said.

ADVANCE FOR RELEASE THURSDAY, OCTOBER 23, 1986

STUDY OF AIDS "ENVELOPE" PROTEIN HAS IMPLICATIONS FOR VACCINE RESEARCH

STANFORD—

One small piece of the AIDS (acquired immune deficiency syndrome) virus may be sufficient to kill cells in the immune system, suggests a new study to be published in the October 23 issue of *Nature* by researchers from Stanford University School of Medicine and four other institutions.

The study also shows that the AIDS virus uses this piece—a specific protein—to bind to and infect susceptible cells, and that this protein is the part of the virus that the immune system targets in attempting to fight off an AIDS infection.

The findings may have important implications for AIDS vaccine development, said Dr. Edgar Engleman, associate professor of pathology and medicine at Stanford University School of Medicine, in an interview.

Because it appears tc stimulate an immune reaction and is also crucial for the virus' infectivity, "this is the part of the virus which we believe should be the focus of vaccine development," Engleman said.

But the substance's ability—on its own without the intact AIDS virus—to cause cell death raises concern that a vaccine based on this protein could cause AIDS-like damage to the immune system rather than protect against the disease, Engleman said.

The piece is the "envelope" protein, the building block of the AIDS virus' outer shell. This protein alone, without the intact virus, can cause certain susceptible cells in the immune system to fuse together and die, the report concluded.

The report also demonstrated that blood serum capable of neutralizing the AIDS virus contains antibodies directed against the envelope protein.

Engleman's colleagues on the study are Dr. Jeffrey Lifson, a Stanford postdoctoral fellow who led the project in Engleman's lab; Drs. Mark Feinberg and Flossie Wong-Staal of the National Cancer Institute; Drs. Gregory Reyes, Linda Rabin, and Babak Banapour of Gene Labs, Inc. in San Carlos; Drs. Sekhar Chakrabarti and Bernard Moss of the National Institute of Allergy and Infectious Diseases; and Dr. Kathelyn Steimer of Chiron Corporation in Emeryville.

The research was supported by grants from the National Institutes of Health and the Veterans Administration.

The findings could present scientists working on an AIDS vaccine with a dilemma because on one hand, since the envelope protein appears to stimulate a protective immune response in some infected individuals, it could form the basis for an effective AIDS vaccine. But on the other hand, since it appears to promote one form of cell death associated with AIDS, it may be "contra-indicated," said Engleman.

10-20-86

more-

The dilemma could be resolved if scientists can learn more about the process of cell death mediated by the envelope protein, he suggested.

In May, Lifson, Engleman, Reyes and their colleagues Drs. Michael McGrath and Barry Stein, first reported on this process. They observed that in the presence of the AIDS virus, helper T cells—the type of white blood cell the AIDS virus destroys—fuse together to form giant cell conglomerates that eventually die. One infected cell can fuse with several healthy, uninfected cells, the scientists found, rapidly depleting the helper cell population.

The disappearance of helper cells into dying giant cells could contribute to the collapse of immune defenses that is the hallmark of AIDS, Engleman explained.

"If you lose the helper cells, you lose the immune defenses, because without helper cells most of the immune system cannot be activated," he said.

Engleman and other scientists are not certain that this is the major mechanism by which the AIDS virus depletes the immune system of its helper cells. But it may be an important point to resolve in development of an AIDS vaccine based on the envelope protein, he added.

Last month, researchers at two biotechnology companies reported early progress on a potential AIDS vaccine made from a vaccinia virus that was genetically engineered to contain genes encoding key AIDS virus proteins.

When Engleman and his colleagues used the same kind of genetically engineered vaccinia virus to carry AIDS envelope gene into human cells in the laboratory, they observed that the envelope protein initiated the lethal cell fusion process.

"There are a lot of people who think that vaccinia-based vaccines hold great promise, that you can give this kind of genetically engineered vaccine to a person and induce immunity without causing harmful effects," Engleman said.

"But because this vector by itself, without the rest of the AIDS virus, causes such profound giant cell formation, there is reason for concern," he added.

The scientists noted that the concerns are not at this point well enough founded to rule out pursuit of envelope-based vaccines, however.

Engleman said that several laboratories are testing experimental envelope-based vaccines. "They have been able to demonstrate that injection of the envelope protein into animals induces antibodies that neutralize the AIDS virus," he pointed out.

"But because there is no really good animal model for AIDS, it's not going to be until a vaccine is tested in human beings that we will know whether or not it works," he said.

COMPLETE MEDICAL EXAMINATIONS OFFERED STUDY VOLUNTEERS

STANFORD—

Physicians at the Palo Alto Veterans Administration Medical Center are providing thorough medical evaluations free to volunteer patients in order to gain a better understanding of metabolic changes that may be associated with high blood pressure.

There is evidence that patients with high blood pressure have some of the same problems with carbohydrate and cholesterol metabolism as patients with diabetes, and that drugs commonly used to treat hypertension may worsen these problems.

The medical evaluations include a complete history and physical examination, blood and urine testing, an electrocardiogram and an oral glucose tolerance test. In addition, there will be a sophisticated assessment of an individual's glucose utilization.

Although the program is directed primarily at patients with high blood pressure who are not diabetic or obese, people with normal blood pressure are invited to participate.

The program is under the direction of Drs. Gerald Reaven, Brian Hoffman, Arthur Swislocki and their associates. It will take place at the Aging Study Unit at the VAMC.

More information is available by calling 493-5000, extension 4572, from 9 a.m. to 5 p.m. Monday through Friday.

ANATOMY PROFESSOR WILLIAM WALTER GREULICH DIES AT 87

STANFORD—

Dr. William Walter Greulich, Stanford University Medical School emeritus professor of anatomy, has died at the age of 87.

Greulich, perhaps best known for his studies of human growth and as a diplomatic science adviser, died of cardiopulmonary arrest Friday (Oct.10) at the Palo Alto convalescent home where he had moved several years ago from his Menlo Park residence.

Dr. Robert Chase, chief of the division of human anatomy, said Greulich was perhaps best known for co-authoring the definitive **Radiographic Atlas of Skeletal Development of Hand and Wrist**, which documents childhood growth and has been used extensively by pediatricians as a desk reference since the first edition appeared in 1950.

Greulich, who became emeritus in 1964, conducted one of the first developmental studies on childhood victims of the atomic bombing of Hiroshima and Nagasaki. Chase said Tuesday that Greulich continued to maintain contact and follow the medical histories of the victims for many years into his retirement, even though the survey officially ended in 1952.

The Japanese studies provided a wealth of data which have been important to other international studies into the effects of radiation on growth, said another longtime colleague, Dr. Donald Gray, emeritus professor of anatomy.

Greulich "brought great luster to the university because he was so well known....He was a highly distinguished person with a great sense of humor," Chase said.

Gray noted that Greulich also had a political side, reflected in several diplomatic posts. He served from 1961 to 1966 as senior scientific attache for the U.S. embassy in London. Earlier, from 1952 to 1954, Greulich served as science advisor to the U.S. High Commissioner for Germany.

After leaving the London post, Greulich became a special deputy to the director of the National Institute of Child Health and Human Development of the National Institutes of Health in Bethesda, Md.

Born in Columbus, Ohio, in 1899, Greulich graduated with a Ph.B. in biology from Kenyon College in Ohio in 1926. After receiving a master's degree in biology in 1928, Greulich came to Stanford where he received his Ph.D. in anatomy in 1934.

Greulich joined the Yale faculty where he rose to the rank of associate professor in 1939. In 1940, he went to Western Reserve University School of Medicine as a full professor. Four years later he joined the Stanford faculty, and for many years after 1949, he served as executive head of the anatomy department.

A widower, Greulich is survived by two sons, James L. of Whittier, and Richard, of Severna Park, Md; and by six grandchildren and two great grandchildren.

The family prefers that contributions in Greulich's name be made to the Lane Medical Library at Stanford. Funeral services were scheduled Tuesday at Roller & Hapgood & Tinney, 980 Middlefield Road, Palo Alto.

HOSPICE PROGRAM PLANNED BY STANFORD

STANFORD—

Stanford University Hospital's Home Health Care program, which recently marked its first year of helping patients recover from illness while remaining at home, is preparing a hospice program to help those with terminal illnesses.

Kathryn Janz, director of the home care program, said the program will help many patients who want to remain at home during the last weeks of their lives.

Recruitment of volunteers is the major task remaining before the hospice service can be inaugurated. Two open houses will be held this month to explain the program and responsibilities to prospective volunteers. The first will be at 6 p.m. Thursday, Oct. 23, at the Home Health Care office, 437 Webster St., Palo Alto. The second will be at 3 p.m. Thursday, Oct. 30, at the American Cancer Society, 535 Race St., San Jose.

Sharon Beckham, coordinator of volunteer resources for the hospital, said volunteer responsibilities in the hospice program will range from practical support such as helping a patient eat to providing respite for the family or seeing the family through the period of bereavement.

She said volunteers will be asked to make a one-year commitment to the program and those accepted will go through a five-week, 20-hour training program. During the year, they will be asked to attend monthly support group meetings.

"Volunteer involvement in a hospice program is invaluable," Beckham said, "particularly in providing respite to the patients' families. These people really do personalize the care we provide. And they find the experience personally gratifying; they grow as individuals by helping others."

Janz said Stanford decided to offer hospice care because "no one hospice program covers the entire three-county area (San Mateo, Santa Clara and Alameda) where the majority of Stanford patients live."

The Home Health Care service is already positioned ideally for hospice care, she said, because it provides the requisite 24-hour care. In addition, it can help the transition for patients who have been receiving home nursing services and would object to a transfer to a separate hospice program because it would sever relationships that had developed with the nursing service.

10-14-86

more

Some patients, Janz said, also must be psychologically prepared for the transfer from home care to hospice care because they are not yet ready to accept their prognoses.

A principal difference between home care and hospice care, she said, is that in hospice care the patient and his or her family comprise the unit of care. Family members are involved in caring for the terminally ill patient, and they also become clients in a sense because they get bereavement counseling.

Janz described the hospice approach as labor-intensive and "high-touch," compared with the "high-tech" services offered by the hospital. If it becomes necessary for a hospice patient to enter the hospital, she said, the hospice care-givers will be available to offer advice and work with the hospital staff.

One factor influencing Stanford's decision to start a hospice program, she said, was the unusually high percentage of cancer patients receiving home care. Many cancer patients were in effect already receiving hospice care, she explained.

"We also have a lot of patients with end-stage cardiac respiratory diseases," she added.

Hospice patients come from all age groups, but Stanford expects a higher percentage of children than most hospices because the home care service treats substantial numbers of children.

Janz recalls one newborn with major cardiac disorders who "was sent home to die. The parents wanted the child to be with them in a warm, caring atmosphere."

Providing care under such circumstances was similar to the hospice program, Janz said, but it lacked certain aspects of the full hospice services, such as the volunteer component and a bereavement program.

She said another area in which hospice training will expand on the home care service is in development of "a strong expertise in the area of symptom control, particularly in the area of pain, so that a patient will not have to suffer. We will be no longer dealing just with the disease, but dealing with the symptoms."

Janz expects about 200 patients to enroll in the hospice program the first year.

STANFORD SCIENTISTS ISOLATE A NEW CANCER-ASSOCIATED GENE

STANFORD—

A piece of human genetic material which may play a role in causing one form of cancer of the white blood cells has been isolated by Stanford University Medical School researchers.

The discovery will have no immediate impact on treatment methods for the cancer, but the research represents a new approach to studying the molecular basis of certain malignancies, the scientists said.

Alterations of the gene are strongly associated with a form of cancer called follicular (or nodular) lymphoma, a malignancy of the white blood cells known as B cells, which play an important role in the body's immune system, said Dr. Michael Cleary, assistant professor of pathology at Stanford University School of Medicine.

In the United States, follicular lymphoma is the second most prevalent adult lymphoma, after Hodgkin's disease, he said.

By cloning the cancer-related gene, the scientists were able to study the structure of its protein product in detail, Cleary said. An unexpected finding was that the protein product of the gene is related to a product of the Epstein-Barr virus, a virus known to affect the growth of B-cells, Cleary said.

"We now need to study the function of this protein to determine its potential role in the cancer process," he added.

Such studies may eventually result in the development of a new therapy to combat follicular lymphoma, a slow-growing cancer which is difficult to cure using current treatment methods, he said.

The isolation of the so-called "oncogene," one of only a handful associated with human malignancies, was reported in an article in the October 10 issue of the journal *Cell*.

The researchers were careful to point out that it will require further research for the newly found gene to be classified with complete certainty as a human oncogene. But their report presents strong circumstantial evidence that the newly isolated gene should be considered as a provisional member of this class of cancer-associated genetic elements, Cleary noted.

Cleary's colleagues on the work are Dr. Stephen Smith, associate professor of pediatrics, and Dr. Jeffrey Sklar, assistant professor of pathology.

The research was conducted with grants from the National Institutes of Health, the American Cancer Society, and the Lucille P. Markey Charitable Trust, as well as through scholarship funds from the Markey Trust and the Leukemia Society of America.

Oncogenes, which have only been recognized in the past decade, are pieces of the body's own hereditary material, DNA, that are thought to drive the uncontrolled cell proliferation that is a hallmark of cancer.

more

10-13-86

2-2-2

Oncogene research is one of the most exciting and promising areas of basic cancer research. About 50 such cancer-associated genes are known, said Cleary, but "only a handful are clearly associated with human cancers.

"The more we know about oncogenes and their role in controlling cell division, the better able we might be to design new anti-cancer therapies," Cleary said.

Most of the time they are normal segments of genetic material, called "proto-oncogenes," that play important and needed roles in the body's cells and tissues. But disturbances of these Jekyll-and Hyde genes can turn harmless proto-oncogenes into cancer-causing oncogene forms, which are capable of transforming a normal cell into a cancerous one.

Certain viruses, chemicals, and types of irradiation are among the carcinogenic agents that can trigger such a gene's Jekyll-and-Hyde switchover.

But for the gene Cleary and his colleagues are studying, the trigger seems not to be an environmental agent such as a chemical. It may instead occur due to an error in the normal maturation process of B cells, Cleary suggested.

As B cells mature and become ready to produce disease-fighting antibodies, they must undergo rearrangements of their antibody genes, Cleary explained. In some cases, this shuffling of DNA may go awry, he said.

In the case of follicular lymphoma, for example, scientists have discovered that in 90 percent of patients the cancerous cells have a characteristic pattern of broken and reattached DNA, in which pieces from two separate chromosomes are translocated, or trade places.

Cleary and his colleagues showed that this DNA translocation breaks an antibody gene and the candidate proto-oncogene in half, then abnormally rejoins the two to create a hybrid gene.

They used advanced techniques of molecular biology to identify and isolate the abnormal product of the hybrid gene that was created by the translocation process.

The scientists went on to show that the candidate proto-oncogene is quiescent in some B cells but when it is translocated to the new site on a different chromosome, it becomes very active. The scientists believe that this abnormal "awakening" of the gene could be involved in triggering the follicular lymphoma.

Now, the researchers want to study the gene in more detail and analyze the function of the protein whose structure it specifies, in the hope that they can design agents to inhibit or block its activities.

"In the future, we're going to find more and more genes like this," Cleary predicted, "by performing molecular analysis of chromosomal translocations.

"The list of cancers that are associated with specific chromosomal translocations continues to increase as we refine our methods for detecting these abnormalities," he said.

PLASTIC SURGERY TARGETS FUNCTION, NOT JUST APPEARANCE

STANFORD—

Electrodes, computers and wood screws, as well as reattached muscles or blood vessels, help plastic surgeons make damaged bodies work—not just look—better.

Dr. Lars M. Vistnes, head of the Division of Plastic and Reconstructive Surgery at Stanford Medical Center, and Dr. Vincent R. Hentz, head of the Division of Hand and Upper Extremity Surgery at Stanford, stressed the rehabilitative function of their medical art during a free public Progress in Medicine Lecture at Stanford Tuesday night (Oct. 7).

Vistnes said that while individual practices vary widely, the average plastic surgeon spends no more than 40 percent of his or her time on purely cosmetic surgery.

Vistnes said that a key goal of plastic surgery is to improve somebody's body image, and "it is just as crippling to a person's body image to have a part that doesn't function correctly, even if it looks all right, as it is to have a part that doesn't look right but functions moderately well."

Hentz discussed advances in the use of computers to provide control and function in otherwise unusable muscles. Electrodes, implanted in muscles, are in turn controlled by computers, which give a paralyzed patient the ability to perform tasks. Such research accomplishments are an outgrowth of the plastic surgeon's art, which in the past has been stereotyped as simply a means to improve a patient's appearance.

"More Than A Pretty Face" is in fact the title of the Progress in Medicine series, which continues for the next two Tuesdays (Oct. 14 and 21) with speakers on a wide spectrum of the specialty.

Among other recent advances in reconstructive surgery is the ability to use screws—which look like ordinary wood screws—to hold broken bones in place to facilitate mending. The process allows persons to exercise their limbs during the healing process to prevent the stiffness that results form being immobile in a cast for a long time, Hentz said.

An important finding in recent years is that nerves can be reconnected, allowing muscles, for example, to regain function when they're transplanted from one part of the body to another.

10-8-86 -more-

For example, Vistnes noted that moving a toe to a finger is justified, because the foot can maintain nearly normal function, while the improvement to the hand is significant and makes the effort worthwhile.

Both Hentz and Vistnes noted that many of the important developments in plastic surgery have resulted because of microsurgery techniques. Surgeons can connect nerves and blood vessels using microscopes to guide their highly intricate task.

Other uses of plastic surgery include repair of damage from trauma or following cancer surgery, Vistnes noted.

Vistnes, a professor of surgery and 15-year Stanford veteran, said the name plastic in his field "refers both to what we do and how we do it." Many operations are intended to repair injuries, and often the surgery involves unique situations. Therefore, the surgeon may be faced with a procedure that in its entirety has never been done before.

"But all of the parts of the surgery have been done (in other contexts) before, so it's a matter of having a plastic mind and putting all of the correct elements together," Vistnes explained.

The next lecture in the series, Tuesday, Oct. 14, features Dr. Seung K. Kim, assistant professor of surgery, who will discuss "Plastic Surgery After Mastectomy"; and a talk on cosmetic surgery, "Mirror, Mirror on the Wall," by Dr. Robert M. Pearl, clinical associate professor of surgery and assistant physician-in-chief of Kaiser PermanenteHospital, Santa Clara.

The final talk in the series, Tuesday, Oct. 21, features "The Future of Microsurgery," Dr. Joseph M. Rosen, assistant professor of surgery at Stanford and Chief, Division of Plastic Surgery at the Palo Alto Veterans Administration Medical Center; and Dr. Donald R. Laub, clinical associate professor of surgery, who will talk about "The Interplast Story," a service by U.S. medical personnel to provide volunteer plastic surgery to children in Third World countries who are suffering from birth or other correctable defects.

All lectures in the three-part series begin at 7:30 p.m. in Sherman Fairchild Auditorium at Stanford University Medical Center. Parking is available in a parking lot accessed from Campus Drive West.

INTERNAL MEDICINE SPECIALIST JOINS STANFORD MEDICAL GROUP

STANFORD—

Dr. Jeffrey Croke, a specialist in medicine formerly associated with a multi-specialty group in Colorado Springs, has joined the Stanford Medical Group (SMG).

Croke is the seventh physician to join the group, which is made up of medical school faculty. The physicians provide primary care to patients from Stanford as well as from the local community, including those covered by Maxicare and other health insurance plans. "This is not just a referral clinic," said Dr. Michael Jacobs, director. "Our patients come to us for ongoing primary care."

Patient visits to the five-year-old clinic have increased 25 percent since the introduction of Maxicare, Jacobs said. The number of patients is projected to double in the coming year, he added.

Croke's appointment follows a national search because "he was clearly the most outstanding choice," Jacobs said. He received his M.D. from University of California, Los Angeles, in 1981, and completed his training at University of California, Irvine. After a three-month stint in the Amazon basin in Brazil, where he cared for patients and taught primary care skills to local nurses, he joined the Colorado group.

In addition to caring for patients, Croke said he plans to emphasize teaching residents strong primary care skills. "More students are becoming interested in general internal medicine rather than specialties. The demand is up for primary care physicians," he said.

STANFORD MEDICAL SCHOOL ADMISSIONS DIRECTOR APPOINTED

STANFORD—

Dr. Norman Blank, professor of radiology, has been appointed director of admissions at Stanford University medical school.

In his new position, Blank will oversee the application, selection and matriculation of all medical students.

"My goal is to obtain the very best class each year for the school and to choose students who will benefit most from what Stanford has to offer," Blank said.

Stanford, he explained, is unique in that it offers great flexibility and individual choice in the way students can choose to pursue their medical education. "I don't know any other school that offers the diverse opportunities that we do," he noted.

Students at Stanford medical school have the option of taking five years or longer to complete their medical education. By doing so, they can pursue activities in other nonmedical fields or get involved in research projects.

Appointed by the medical school's senate and committee of five, Blank succeeds Dr. Raymond Clayton, who chose not to renew his term as director.

"We will continue to be vigorous in our recruitment of students from all segments of society," Blank said. "I feel fortunate to have a very hardworking cadre of people working in the admissions office as well as the voluntary efforts of faculty and students. Without their help, we simply could not do our job."

Blank, who came to Stanford in 1962, has been active in medical education in addition to his field of radiology and has received several awards for excellence in teaching.

HEIGHT IS LINKED TO INTELLIGENCE, STANFORD STUDY SHOWS

STANFORD—

A small but significant correlation between height and intelligence in children has been documented by a group of researchers at Stanford University.

While the reasons for the association are unclear, said Stanford pediatrician Dr. Darrell Wilson, a possible explanation may be that shorter children are treated differently by adults than their taller peers.

Short children tend to be babied more than others, Wilson explained.

The difference may also be caused by some intra-uterine damage or postnatal malnutrition that affects height as well as IQ, he added.

Because the researchers' study showed no change in the correlation as the children grew with age, the researchers cautioned against any type of therapy, such as synthetic growth hormone, to enhance growth among short children as a way of increasing intelligence.

The researchers published the results of the study in the October issue of *Pediatrics*, the journal of the American Academy of Pediatrics.

"If anything, this study shows that children should be treated according to their ability, and not height or other physical characteristics," Wilson said.

The scientists analyzed data provided by the National Health Examination Survey conducted by the National Center of Health Statistics during the 1960s to obtain health-related data from a sample of noninstitutionalized youth. They included 13,887 children between the ages of 6 and 17. They also looked at a group of 2,177 children who were tested initially and then again two to five years later.

The data included scores of the Wechsler Intelligence Scale for Children (WISC), which measures intellectual ability, and the Wide Range Achievement Test (WRAT), which measures academic achievement. The study also took into account socioeconomic factors such as family income, race, family size and birth order.

The analysis showed that height accounted for about a two percent variance in the IQ scores of the shortest to the tallest children. There was no major difference between males and females. There was also no difference in the group tested twice, leading to the conclusion that a relative change in height does not necessarily affect IQ scores.

Thus, they suggested, a child's intellectual abilities may be determined early on in life and are not affected by any relative changes in height.

The findings support other studies on the correlation between height and intelligence among adults. "While these studies have methodological flaws, they suggest that the association between height and IQ in childhood persists into adulthood and does not reflect transient differences in relative physical maturity or growth," the researchers said.

The study was funded by the Stanford Center for Study of Youth Development andd Father Flanagan's Boys' Home. Other authors included Drs. Lawrence Hammer, Paula Duncan, Sanford Dornbusch, Philip Ritter, Raymont Hintz, Ruth Gross and Ron Rosenfeld from Stanford's pediatric department and sociology department.

PROGRAMS ON ALCOHOL, DRUG DEPENDENCY SCHEDULED AT STANFORD

STANFORD—

A series of four programs on alcohol and drug dependency will be held this month at the Fairchild Auditorium of the Stanford University School of Medicine.

The hour-long programs, sponsored by the Stanford Alcohol and Drug Treatment Center, will feature four physicians who are experts in various aspects of the field.

Registration for each program will begin at 8 a.m. and the lectures will begin at 8:30 a.m. There will be a question and answer period after each speech. The programs, including dates and speakers:

- Friday, Oct. 10—"Physician Attitudes Toward Chemical Dependency," by Dr. John Chappel, professor of psychiatry at the University of Nevada, Reno.
- Friday, Oct. 17—"Making the Diagnosis," by Dr. Max Schneider, president of the American Medical Society on Alcoholism and Other Drug Dependencies.
- Wednesday, Oct. 22—"Initiating Treatment," by Dr. Jess Bromley, secretary of the American Medical Society on Alcoholism and Other Drug Dependencies.
- "Physician's Role in Treatment," by Dr. William Hazle, medical director of the Stanford Alcohol and Drug Treatment Center. Hazle will also be moderator for the programs.

There will be a fee of $20 for physicians to attend all four sessions. Members of the Stanford University Hospital nursing staff will pay $15 and the cost to other professionals is $20. Medical students and residents will be admitted free.

The program series is offered in conjunction with the California Medical Association and has been approved for credit by the CMA and the California Board of Registered Nursing.

Further information may be obtained by calling Diana Kennedy at (415) 723-6682.

PAIN MAY NOT GAUGE HEART ATTACK RISK

Pain is not a reliable way to judge the seriousness of a heart condition, according to a 10-year study led by a Stanford Medical School faculty member and other researchers for the Veterans Administration.

Dr. Herbert Hultgren, a professor of medicine, says the study of 686 patients at 13 VA medical centers showed some patients with very mild symptoms had very severe underlying heart disease and a high risk of a heart attack or sudden death. On the other hand, a majority of other persons with severe angina—pain caused by narrowed blood vessels in and around the heart—actually had milder forms of the disease with less chance of a heart attack.

In all, 43 percent of the patients with severe angina were considered to have a high risk of heart attack or death. But nearly as many, 34 percent of the patients with mild symptoms, were also deemed to have a high risk.

Hultgren, who practices at the Palo Alto Veterans Administration Medical Center, recommends that any patient with angina—mild or severe—should have an exercise treadmill and other diagnostic tests to determine the risk of heart attack.

If risk is high, a variety of options, including surgery or medication, can be considered.

BEAUTIFUL MODELS MAY NOT MOTIVATE FITNESS

Television and magazine ads featuring very fit and slim people may be a major deterrent to get people to exercise regularly, says William Haskell, Ph.D., a Stanford University exercise physiologist.

"Pictures of beautifully fit men and women lead to the idea that everyone must achieve and look like that," says Haskell, who serves as associate director of the Stanford Center for Research in Disease Prevention.

But Haskell says the reality is that "many routine activities such as brisk walking if performed regularly produce substantial health-related benefits." Besides the well-known advantage of helping to reduce heart attack risk, persons who exercise regularly gain myriad other advantages—helping the body in how it uses both fats and sugar, for example, or improving blood clotting mechanisms.

The ads are misleading if they portray a country of beautifully fit people. "National statistics show that 80 percent of men over 40 do not participate in any regular vigorous exercise," says Haskell.

The optimal amount of exercise varies for each person, depending on age, health and recent activity. However, for most adults, 30 to 40 minutes of moderate intensity activity relative to their own capacity will result in substantial health and performance benefits, says Haskell, who cites brisk walking, cycling, swimming or active gardening as examples of activities which can produce the desired effects.

PATIENTS NEED TO PLAN FOR HOSPITAL RELEASE

Shorter hospital stays mean patients need to plan for their discharge more carefully if they are going to be comfortable when they return home, notes a discharge planner at Stanford University Hospital.

"With rising health costs, a hospital is not going to serve the function of a convalescent home, and so people are increasingly being sent home earlier," says discharge planner Liza Taft.

Both the need for and availability of home care services are increasing rapidly, Taft says, as medicine improves and as costs dictate shorter hospital stays. "Hospital beds are being reserved for the truly ill, and the modern hospital's role as a convalescent facility has not been feasible for many years," says Taft.

"Home care programs, which send either skilled caregivers or practical help into the home, are one answer," Taft says. But there are a lot of other services available in many areas. Some communities offer an emergency free grocery delivery service by volunteers or markets, while in other areas, volunteers will bring complete meals to recuperating patients at home. Some communities have available an emergency communications system which summons help at the touch of a button when a user becomes incapacitated.

The time to begin investigating these services is not the last day of the hospital stay. When hospitalization is planned in advance, such as for elective surgery, persons would be well advised to make arrangements before admission for the help they'll need when they get home, she says.

Taft advises that patients should be good consumers and ask to see a social worker or discharge planner before their release so that arrangements can be discussed.

SWAPPING HARD LIQUOR FOR BEER OR WINE IS DECEPTIVE

People who switch from hard liquor to wine or beer in an effort to avoid alcoholism aren't helping themselves, says the medical director of the Stanford Alcohol and Drug Treatment Center in Palo Alto, Calif.

"Alcohol is alcohol, and it offers the same potential for addiction in whatever form it's consumed," says Dr. William Hazle, a psychiatrist.

For example, a standard 12-ounce bottle or can of beer, a four-ounce glass of wine or a shot of liquor all provide the same alcohol content, notes Hazle. "Someone who thinks he is cutting back on alcohol by substituting three or four beers for three or four drinks of hard liquor is kidding himself," he adds.

If a person thinks he or she might have an alcohol problem, the only prudent move is to stop drinking and/or seek professional help, particularly if quitting feels difficult, Hazle explains.

HONESTY IN EMERGENCY CAN SAVE A LIFE

Honesty is a good idea in most situations, but in the emergency department it can mean the difference between life and death.

Dr. Ricardo Martinez, director of clinical services for the Emergency Department at Stanford University Hospital, says that patients or family members sometimes withhold crucial information for fear that it will embarrass them or get them in trouble with the law.

Patients who have overdosed on illegal drugs and fear arrest often won't tell emergency personnel, "and this quite simply means that we don't often have enough information to start the appropriate treatment to try and save their lives," says Martinez.

"This is particularly tragic when it involves young children who have somehow obtained and ingested their parents' drugs. True, the parents are already in trouble, but withholding information doesn't make either their legal or personal problems any easier."

A majority of withheld drug information involves presciption drugs which people are embarrassed to tell emergency personnel about, says Martinez. An example might be medication prescribed for a mental illness.

"The hospital emergency department is no place for vanity," he says. "The doctors and other health personnel are not going to make you feel embarrassed. When you tell them about your medication, their main reaction will almost always be gratitude for making their work possible."

PACIFIERS NOT ALWAYS GOOD FOR TEETH

Pacifiers in one form or another have been given to teething children for centuries, but recently questions about them have been raised.

The devices, now made mostly of rubber or plastic, can be useful for relieving or diverting the pain of emerging teeth. But the constant pressure applied by some tots could result in improper dental development, particularly when children continue to use them after their teeth have already penetrated the gum at about age 2, says Dr. Fernando Mendoza, assistant professor of pediatrics at Stanford University School of Medicine.

Constant biting on a pacifier with functional teeth could cause them to grow in at an angle, he says. Such buckteeth create an appearance problem and could interfere with proper chewing, adds Mendoza, who practices at Children's Hospital at Stanford.

However, for infants, a pacifier may be better than chronic thumb sucking, so if a teething youngster must use a pacifier, Mendoza advises parents to wash the device in detergent and boil it for 10 minutes when new. Ideally, it should also be washed before each use, he says. Flat pacifiers more closely simulate a mother's nipple and are potentially less damaging than round pacifiers, Mendoza says.

"Always make sure the pacifier is intact and doesn't contain cracks which would allow the baby to bite off and swallow a portion," he explains.

"And most of all," he says, "never tie a cord to a pacifier or any item your child might use. Children could wrap it around the neck and choke themselves."

HT3/ 4-4-4

ASPIRIN FOR CHILDREN NEEDS SPECIAL CAUTION

Check with your physician before giving aspirin to children under age 16, especially to relieve symptoms of chicken pox or influenza, says Dr. Michael Jacobs, of Stanford Medical Group.

The common and ordinarily safe medication has been associated with Reye's syndrome, a disease of uncertain origin which strikes children after they have already developed symptoms of chicken pox or influenza. Jacobs, a clinical associate professor of medicine who specializes in primary care at Stanford University, says that while more research is needed to show conclusively if Reye's and aspirin are linked, the association is sufficient to prompt a warning to parents.

Symptoms of Reye's usually appear at the time a child should be recovering from the flu. The first sign is persistent vomiting. If left untreated, that condition can be followed in about six hours by extreme sleepiness, disorientation, hostility-combativeness, followed by loss of consciousness and sometimes death.

If a child recovering from chicken pox or flu develops these symptoms, he or she should be seen by a physician immediately.

Jacobs notes that widely sold aspirin substitutes, made from acetaminophen and marketed under a variety of popular national brands, appear to be safe and free of any association with Reye's.

CONTACT LENS USE REQUIRES CARE AND CAUTION

A Stanford University Medical School eye specialist has some simple but important advice for contact lens wearers: clean them regularly to avoid infection and never keep them in the eye longer than recommended.

Dr. Michael F. Marmor, who heads the Division of Ophthalmology, says that contact lenses can give years of good service if cared for properly. But since they rest directly on the eye, they carry the seeds of disaster in the form of particles or bacteria which become lodged beneath them.

The risks of scarring or infection become greater the longer a lens is worn without cleaning. Lenses which are designed for daily wear should never be worn longer, Marmor believes. Extended wear lenses carry an added risk of infection and many eye doctors are now saying they shouldn't be used unless there is a strong reason to do so, says Marmor.

- more -

INJURIES, IF NOT FALLS, CAN BE PREVENTED

Falls can't always be prevented, but many times the injuries which result can be avoided.

Dr. Ricardo Martinez, director of clinical services for Stanford University Hospital's Emergency Department, says elderly people and very young children are the most likely to be seriously injured when they fall.

Martinez says a common injury occurs when elderly people stumble in the dark after they get up in the middle of the night to use the bathroom—a trip seniors take more often than younger folk.

A few simple steps will help avoid injury. Clear the pathway from the bed to the bathroom, put padding on sharp objects, or remove those objects from the pathway. Night lights placed along the route are inexpensive, don't use much energy, and are very effective, he says.

Falls in the home accounted for 4,850 deaths among persons 65 and older in the United States in 1985, says the National Safety Council in Chicago.

MAGNETS OFFER CLEAR BODY PICTURES WITHOUT RADIATION

Magnets are increasingly helping to provide clear pictures of body organs, tissues and even bones without the radiation of X-rays.

And for most uses, the new technique of magnetic resonance imaging (MRI) not only eliminates the dangers of radiation, but also offers higher quality diagnostic images than X-ray, says Dr. Dieter Enzmann, associate professor of diagnostic radiology and director of Stanford University Medical Center's MRI facility.

Certain kinds of abnormalities in soft tissues in the body, including the brain and spinal cord, can be accurately imaged and analyzed for diagnostic purposes, says Enzmann. Some of these soft tissue abnormalities do not show up on X-ray images.

In addition, MRI is superior to other techniques because pictures can be taken at any angle, not just in cross section as in CT-scans, a form of X-ray. With MRI, physicians can visualize and chart brain tumor size, for example.

MRI is expensive and the latest techniques are currently available at only a few centers. Even though new centers are being started regularly, MRI is not likely to replace X-rays for many routine uses, such as diagnosing broken bones. However, the technique is potentially more accurate even for that common use, Enzmann explains.

MRI eliminates the risk of radiation. It is considered extremely safe, although it usually can't be used by persons who have metal implants, such as a pacemaker or brain aneurism clips.

The powerful magnetic field interacts with electrically charged atomic particles, protons, in the body. Energy is released from protons and is recorded and rendered into an image by the MRI system's computers.

NURSING RESEARCH DOESN'T MEAN ASSISTING DOCTORS

Editors: photos available on request

STANFORD—

Dr. Robinetta Wheeler, a Stanford University Hospital (SUH) nursing supervisor, bristles whenever someone says nursing research means collecting data for physicians.

It doesn't, and she helped organize a recent symposium, or rounds, to highlight that nursing's brand of research is distinct from the medical research performed by physicians. The nurses target questions directly related to the care of patients, including ways of making the work of nurses more efficient, said Wheeler. She is clinical nursing coordinator (head nurse) of an SUH patient unit and holds both an R.N. degree and a Ph.D. in medical sociology.

Wheeler and her colleagues were anxious that the doctors and others they work with on the units see what they are doing scientifically, so they set up 10 booths outside the hospital cafeteria. Not only doctors, but fellow nurses, other employees and even visitors enroute to lunch stopped and viewed exhibits or posters telling about projects. Most of the nurses were available to answer questions, and most of the participants passed out copies of research papers related to nursing projects, including journal publications nurses had authored.

In a five minute stop at a couple of booths, lunch goers could have learned, for example:

- That Claire B. Mailhot, assistant director of nursing and director of the SUH operating room; Linda Slezak, assistant OR director; and Marianne Zalar, a former nurse researcher at Stanford, had collaborated with two colleagues from Britain in an infection control study. The research, published in the September/October issue of *Nursing Research* journal, validated the effectiveness of cover gowns in preventing bacterial contamination of scrubsuits when nurses temporarily exit the OR.

- Four nurses in the Intensive Care Nursery, Jane Earenfight, Sandy Chapman, Pat Carter, and Arlene Sheehan, found no statistical differences between rectal and easier-to-administer axillary temperatures among infants nursed under radiant warmers.

"The results of this study enabled us to revise our nursing practice of requiring infants under radiant warmers to have rectal temperatures taken routinely," the authors said in an abstract published in the newsletter *Nurse Inquirer*.

• Two nurses at the Palo Alto Veterans Administration Medical Center, Anne Grillot and Pat McCarthy, found in a study conducted at several area hospitals, including Stanford, that nurses who work in intensive care units had a higher level of death anxiety than their non-ICU colleagues. This anxiety occurred even when conscious efforts were made to counteract the potential stress. Grillot and McCarthy's study has been submitted for publication.

Nurses have been encouraged for many years to undertake research projects, and Wheeler noted that the current emphasis at Stanford is on unit-wide efforts.

"We encourage a group of staff nurses to identify areas of concern and join together to study the issue," she said. Although there is no precise count of how many projects are currently underway at SUH, Wheeler noted that 48 current projects in various stages of completion are listed with the Medical Center's Human Subjects Committee. That group must approve the safety and appropriateness of all projects involving patients or volunteers.

Wheeler said she is particularly interested in chronic illness in the elderly, as well as studies to find ways of bringing families into the caregiving process.

And one of the posters at the recent event addressed the issue of family involvement in hospitalization, Wheeler noted. That research was completed by Dr. Nancy Lovejoy, a member of the nursing faculty at UC San Francisco.

"Traditionally, family visitors to the hospital have been viewed as a nuisance. Lovejoy found that is changing, and one of the things she looked at was how to help fulfill visitor needs while they're at a hospital offering support to a relative," said Wheeler.

"Patients come from family groups and when they leave the hospital they return to a family group. To ignore that while they are in the hospital is ridiculous.

"Lovejoy's research is particularly timely, because with shorter inpatient stays, family members will be called upon increasingly to help with care at home. The more we can help them learn skills, the more effective they'll be at home, and the patient will be the big beneficiary," Wheeler said.

STUDY PLANNED OF HYPERTENSION DRUG WITH CHOLESTEROL-LOWERING POSSIBILITIES

STANFORD--

Physicians at the Palo Alto Veterans Administration Medical Center are seeking hypertension sufferers for a study of prazosin, a hypertension drug that seems to lower blood cholesterol levels.

In contrast with the apparent effect of prazosin, many drugs now used to treat high blood pressure result in higher cholosterol levels.

Volunteers will be given a free, thorough medical examination, as well as free blood pressure therapy for the duration of the study.

Participants must be between the ages of 21 and 60 and have hypertension, but otherwise be in good health. They must be able to come to the VAMC at regular intervals of roughly two weeks for blood pressure checks and metabolic measurements.

The program is under the direction of Drs. Gerald Reaven, Brian Hoffman, Arthur Swislocki and their associates. It will take place at the Aging Study Unit of the Palo Alto VAMC, although some measurements will be performed at the Clinical Research Center at the Stanford University Medical Center.

More information can be obtained by calling 493-5000, ext. 4572, from 9 a.m. to 5 p.m. Monday through Friday.

TYPE A PATIENTS ARE NOT AT EXTRA RISK FOR SECOND HEART ATTACK

STANFORD—

Type A patients who suffer heart attacks do not have a significantly greater risk of a repeat attack than Type B patients, according to a study by researchers at the Stanford University School of Medicine.

Type A behavior is considered coronary prone and is characterized by aggression, impatience and signs of stress. Type B behavior is more relaxed and is considered less of a coronary risk.

In a paper presented Monday at the American Heart Association's Scientific Sessions in Dallas, Dr. Charles A. Dennis, assistant professor of medicine, reported on studies of 303 men about 50 years old who were recovering from heart attacks. Sixty-one percent of the men were classified as Type A and 39 percent as Type B on the basis of structured personality interviews.

There were no significant differences between Type A and Type B patients in the frequency or type of coronary events in a six-month followup period, Dennis said.

However, he said, there was a difference in coronary events when the patients were classified as high-risk or low-risk according to historical and clinical variables. The high-risk category included 73 percent of the patients who had a subsequent medical event—cardiac death, nonfatal myocardial infarction or nonfatal cardiac arrest—and 60 percent of those who had a surgical event—coronary surgery or angioplasty.

FOR RELEASE 11:30 A.M., MONDAY, NOV, 17

EARLY RETURN TO WORK IS GENERALLY OK FOR PATIENTS RECOVERING FROM HEART ATTACK

Patients recovering from heart attacks can return to work relatively soon without increased risk after exercise testing to determine their risk for future attacks and their physical capacity, Stanford University Medical School researchers reported Monday.

Dr. Charles A. Dennis, assistant professor of medicine, outlined results of the Stanford study at the American Heart Association's Scientific Sessions in Dallas.

He said 203 men about 50 years old who had suffered uncomplicated heart attacks were divided randomly into two groups: 102 received usual care and 101 were given an Occupational Work Evaluation.

This evaluation consisted of a treadmill test performed 21 days after the heart attack, followed by an explicit return-to-work date based on the test results. The usual care group received no such return-to-work instruction.

Those in the group receiving the Occupational Work Evaluation returned to their jobs a median of 51 days after heart attack, Dennis said, while those in the usual care group didn't get back to work until a median of 75 days after heart attack.

In both groups, the number of patients experiencing cardiac events within 6 months was small: there were deaths in 1.5 percent, recurrent heart attacks in 2 percent and revascularization procedures in 13 percent.

After 6 months, 89 percent of those in the work evaluation group and 87 percent of the usual care group were still working, Dennis reported.

FOR RELEASE 12:15 P.M., MONDAY, NOV. 17

HEART'S "WORKHORSE" CHAMBER PUMPS LIKE A BELLOWS

The heart's major pumping chamber, the left ventricle, uses a "bellows" motion to push blood out into the body, Stanford Medical School researchers reported Monday, Nov. 17 at the American Heart Association meeting in Dallas.

This kind of pumping action is highly efficient and may minimize the blood's ability to stagnate or clot inside the heart, according to Dr. Craig Miller, associate professor of cardiovascular surgery, Dr. Neil Ingels of the Palo Alto Medical Research Foundation, and their colleagues.

The scientists used a computer to analyze X-ray "movies" of heart action in 15 heart transplant patients. The picture they obtained of the left ventricle's pumping action contradicts previous theories of how the left ventricle pumps blood.

—30—

FOR RELEASE 9 A.M. TUESDAY, NOV. 18

WRINGING ACTION OF HEART DETECTED

Stanford Medical School researchers have discovered the function of fibers in the heart's wall, which have been known but unexplained since Leonardo da Vinci's time.

The fibers "wring" the heart's left ventricle like a washcloth, as it ejects blood out into the body, reported cardiology fellow Dr. David Hansen, Dr. Craig Miller, associate professor cardiovascular surgery, and their colleagues Tuesday, Nov. 18 at the American Heart Association meeting in Dallas.

The wringing motion called torsion, which had never before been detected, possibly allows the heart to store energy when it ejects blood, and then use this energy to refill its chambers, the scientists believe.

Torsion also may provide physicians with a relatively simple way to measure the contractility of heart muscle.

—30—

FOR RELEASE 9 A.M., TUESDAY, NOV. 18

ULTRASOUND MAY REVEAL HEART TRANSPLANT REJECTION

Ultrasound—very high frequency sound waves—may provide a new non-invasive method for diagnosing rejection in heart transplant patients, Stanford University Medical School researchers suggest.

In a study of 22 heart transplant patients who experienced rejection episodes, ultrasound detected characteristic changes in the function of the heart's left ventricle, reported cardiologist Dr. Hannah Valantine, and her colleagues Tuesday, Nov. 18 at the American Heart Association meeting in Dallas.

Currently, rejection is diagnosed by heart biopsy, an invasive procedure which may be painful and inconvenient to the patient. Ultrasound measurements, which are easily performed and thought to be safe, might help reduce the number of biopsy procedures performed.

—30—

FOR RELEASE 11:45 A.M., TUESDAY, NOV. 18

BREATHING AND HEART RATE CHANGES LINKED IN HIGH-ALTITUDE STUDY

Changes in the breathing patterns of subjects sleeping at high altitudes were accompanied by changes in their heart rates, Stanford University Medical School researchers reported.

Dr. Herbert Hultgren, professor of medicine at the Stanford University School of Medicine and a staff cardiologist at the Palo Alto Veterans Administration Medical Center, and his colleagues studied seven male subjects in a low-pressure chamber that simulated a 40-day ascent of Mt. Everest. They found changes in heart rates at 18,000 to 25,000 feet, Hultgren reported Tuesday, Nov. 18 at the American Heart Association meeting in Dallas.

It has been known for some time that people sleeping at altitudes above 10,000 feet often have periods during which their breathing stops for a few seconds.

Hultgren's study showed those changes in breathing are sometimes accompanied by changes in heart rate and rhythm.

Although the study shows a close relationship between breathing and heart rates under certain conditions, he said, "it does not indicate any danger to anybody who might experience the condition."

—30—

FOR RELEASE 3 P.M. TUESDAY, NOV. 18

CARDIAC TRANSPLANTATION IN CHILDREN AND ADOLESCENTS YIELDS ENCOURAGING RESULTS

Heart transplants provide an "effective therapy for children and adolescents with end stage heart disease," Stanford University Medical School researchers said Tuesday, Nov. 18 at the American Heart Association meeting in Dallas.

Among 27 patients, aged two to 18, transplanted at Stanford in the last five years, there are 22 survivors, 100 percent of whom have achieved rehabilitation and resumed normal life, said cardiovascular surgeon Dr. Vaughn Starnes and his colleagues.

Like all transplant patients, the children must continue lifelong drug treatments to prevent rejection of the transplanted organ, and they also require treatment for high blood pressure, the researchers reported.

But the rates of rejection and infection in the children are similar to those observed in adult transplant patients, they noted.

Further time is needed before doctors will fully know to what extent chronic immune suppressive drug therapy affects children's growth and development. But so far, the researchers believe there is cause for "cautious optimism" about the future for heart transplants in young patients.

FOR RELEASE 4:45 P.M., TUESDAY, NOV. 18

CLUES TO WHICH TRANSPLANT PATIENTS ARE LIKELY TO GET CORONARY DISEASE

Stanford University Medical School researchers have identified two factors that could help predict which one-third of heart transplant patients will develop coronary disease within five years after their operations.

The findings, presented Tuesday Nov. 18 at the American Heart Association meeting in Dallas, suggest that an older donor heart and a recipient's serum triglyceride metabolism (one type of blood lipid) are the most likely factors, among those studied, to play a role.

In a review of 132 patients transplanted since 1979, Dr. Shao Zhou Gao and his Stanford Medical School colleagues found that the age of the heart donor and the recipient's serum triglyceride levels one year following transplant were significantly higher in the 44 patients who developed accelerated coronary disease than in those whose hearts remained healthy.

Other factors such as blood cholesterol profiles, extent of donor-recipient tissue matching, age of the recipient, drug therapy and number of rejection episodes were similar in both groups of patients, the researchers found.

Physicians would like to better understand why some transplant patients develop coronary disease since it affects long-term survival prospects in approximately one-third of transplant patients and can cause sudden death.

—30—

FOR RELEASE 10 A.M., WEDNESDAY, NOV. 19

BIOPSY PREDICTS WHICH CARDIOMYOPATHY PATIENTS WILL BENEFIT FROM DRUG THERAPY

Stanford University Medical School researchers have found a test that may help predict which patients with cardiomyopathy are likely to benefit from treatment with the beta-blocker drug, metoprolol, they reported Wednesday Nov. 19 at the American Heart Association meeting in Dallas.

Some patients with cardiomyopathy—deterioration of the heart muscle—who are given the beta-blocker drug can further deteriorate, while others benefit from the therapy. Since simple tests have proved unreliable in distinguishing the two types of patients from each other, cardiologist Hannah Valantine and her colleagues explored the use of myocardial biopsy, a procedure in which a tiny piece of heart muscle is snipped off with a pincer threaded into the heart.

In a study of 41 patients with cardiomyopathy, they found that among the 21 patients whose biopsies showed only mild lesions, all but one tolerated beta-blocker drug therapy. In contrast, 11 out of 20 whose biopsies showed severe muscle damage had to be taken off the drug.

This suggests that patients whose biopsies reveal only mild or moderate abnormalities should benefit from beta-blocker drugs with minimal risk of deterioration, the researchers concluded.

NEW QUARTERS TO MEAN EXPANDED OPERATIONS FOR STANFORD'S PAIN MANAGEMENT UNIT

STANFORD—

Dr. Lorne Eltherington is an authority on the treatment of pain, but he makes it clear that there's not much he can do to end the suffering of many chronic pain victims.

What he can do—and what he tries to do repeatedly—is teach them to control or cope with their pain themselves. That, to Eltherington, is the real key to dealing with chronic pain.

"Disability, it seems to me, is where the bottom line is, not pain," he said.

"There are many treaters who are only looking at the response of the patient to pain in the sense of 'Do you hurt more or less?' What we really should be doing is looking at the patients in terms of function. Are they working, are they doing the relaxation/entertainment exercises that they used to do?

"If indeed you have restored them from being in a chair all day to doing the kinds of things that they want to do, as far as I'm concerned, that's success."

Eltherington, an anesthesiologist, is director of Stanford University Clinic's pain management unit, which will move beginning Friday, Nov. 14, from the Hoover Pavilion into more spacious quarters on the second floor of the Clinic building in the main Stanford Medical Center.

In the new quarters, he hopes to be able to see more patients and to have the pain unit become more involved in research on the causes and treatment of pain.

He'll also have more ready access to the many resources of the Medical Center, which makes it easier to pursue the multidisciplinary approach he says is essential in the modern treatment of pain.

Stanford's pain unit, Eltherington says, includes "psychology, occupational and physical therapy, psychiatry, medicine and all the various consult services at Stanford such as neurosurgery and orthopedic surgery. That's the trend in the business—coming to multidiscipline programs—because pain is such a multifaceted problem that it really does cross a lot of specialty boundaries."

Eltherington is even willing to use the services of specialists not connected to the Medical Center—such as an acupuncturist. As far as he is concerned, any technique that helps patients is worth trying. "We use things like biofeedback, stress reduction, self-hypnosis," he says. "We've had patients involved in yoga and Transcendental Meditation."

Those techniques may produce some relief from pain, but what is equally as important to Eltherington is they teach patients to help themselves.

"The problem with patients who have chronic pain," he said, "is that they have no control, or they're unwilling to accept control, of their own kind of destiny. They keep coming to treaters and saying, 'Doctor, help me,' rather than saying, 'Well, I've got this problem, I've had it for many years and I'm probably going to have it for the rest of my life. Now what am I going to do about it.' "

Eltherington emphasizes he is not talking about acute pain—pain resulting from a recent injury and destined to ease with time—or the pain of terminal cancer. The chronic pain is usually something that has troubled the patient for years, and persists despite all attempts to treat it.

There has been striking progress recently in some methods of treating acute pain and cancer pain and Eltherington plans to incorporate those methods in the new quarters.

One technique involves the use of catheters implanted under the abdominal skin that can be used for the injection of small amounts of narcotics directly into the area where the pain is centered. This allows the use of much smaller amounts of narcotics than those administered orally or by muscle injection and consequently reduces toxicity.

The catheters can be attached to a device that will continuously administer the narcotics, or they can be set up so that nurses, or the patients themselves, can periodically administer the injections. The catheter treatment can be used to ease the pain of cancer patients at home or help any post-operative patient with a great deal of pain who is still hospitalized.

Another new device is called a dorsal column stimulator. It features a thin wire containing electrodes that is also tunneled under the skin in the area of the pain. Over the skin there is a small black box that sends electrical impulses to the wire. The patient can send electrical messages of varying intensity and duration that stimulate the dorsal columns of the spinal cord.

If the device provides pain relief, it can be left in for long periods of time, Eltherington says. It is used primarily for treatment of patients who have had multiple back surgeries but still have pain, or paraplegic patients who have pain from below the level of their spinal cord damage.

The dorsal column stimulator is a refinement of a device frequently used for chronic pain treatment that is called TENS, for trans-electrical nerve stimulation. Eltherington describes TENS as "very much like acupuncture that the patient takes home." Patients wear electrodes at the pain sites and have a small black box with a battery that they can use to stimulate the skin and get relief from pain.

TENS can be effective for many chronic pain patients, Eltherington said, but he noted the effectiveness often is diminished by a phenomenon of pain treatment:

"The response to TENS in the chronic pain population is probably about 90 percent over the first few days to weeks. At the end of a month, it's probably down to less than 50 percent. And at the end of a year, we're probably dealing with around 10 percent success.

"It's like many things in pain therapy. There's a very high initial success, because people with chronic pain want to hurt less. Then there's a very rapid falloff to where you level off at a 5-15 percent success over long periods of time."

That initial reaction to many pain remedies, coupled with the intense desire of patients to escape suffering, produces a "real problem" in pain treatment, Eltherington said.

"All these new treatments and new devices come on the market with enormous hope," he said. "Pain patients read about them and they phone you and say, 'I want to try brand X.' And sure enough brand X really helps them. Then they invest a thousand dollars in brand X and in one month they say, 'Gee, Doc, this didn't work.'

"There's an enormous amount of scam connected with chronic pain patients. They'll buy anything and they'll really let you do anything to them. . . They really are desperate in terms of accepting almost without thought anything—any injection, any procedure, any device, any drug—that will promise them even a modicum of pain relief."

But the solution to their problems, Eltherington emphasized, lies within the patients themselves.

"The more control they can obtain, the better their chances are for long-term functional increase and even pain reduction," he said. "The more they depend upon other people, the less the long-term success, in terms of either pain relief or increased function."

One major step in self-control, Eltherington said, is to eliminate dependence on pain-killing drugs. Drugs contribute to depression, anxiety and social withdrawal—all of which compound the problems of pain. In addition, he said, the pain sometimes becomes "secondary to an enormous dependency on narcotic drugs that are almost without exception contraindicated in chronic pain management."

Besides rejecting drugs, there are positive steps the chronic pain patient can take, such as losing weight or exercising. (Excess weight and flabby abdominal muscles are often "major components of chronic low back pain," Eltherington said.)

The most positive step, however, is likely to be psychological, the determination to get on with their lives as much as possible despite the pain.

That's why, Eltherington says, "I tell patients I don't much care about how much pain they have. What I really care about is how much disability they have."

NEW CLOT-BUSTING AGENT MAY HELP HEART ATTACK VICTIMS, BUT IT'S "NO PANACEA," SCIENTIST SAYS

STANFORD—

A shot in the arm that stops a heart attack in progress may be on the medical horizon, a researcher told a meeting of scientists Friday, Nov. 7 at Stanford University School of Medicine.

But a shot that could be administered at the first sign of a heart attack by a doctor, relative, or even the heart attack victim, will be "very tricky" to develop, warned Dr. Burton Sobel, professor of medicine and director of the cardiovascular division at Washington University School of Medicine in St. Louis.

"It will require serious investigation with rigorous controls . . . as well as close medical surveillance and highly educated patients . . . if we don't want to do more harm than good," Sobel told an audience composed primarily of scientists and physicians at the fourth annual symposium of the Program in Molecular and Genetic Medicine at Stanford Medical School.

The shot would contain a new blood clot-dissolving agent that has shown great promise in clinical tests worldwide for reducing damage and sudden death due to heart attack.

The agent—called tissue-type plasminogen activator, or t-PA—has dissolved obstructing clots in 70 to 75 percent of several thousand patients worldwide, when injected into the coronary blood vessels within one hour of the onset of heart attack symptoms, Sobel reported.

An estimated 500,000 people in the United States die each year from heart attacks, Sobel said.

"But we are still a long way from saving lots of lives," he cautioned.

Right now, t-PA is administered directly into the blood vessels by means of intravenous lines. Scientists do not yet know how to get enough of the substance into the heart when it's given by a simple injection into the muscles, he said, although exciting new research on "absorption enhancement" agents may lead to a solution.

In addition, because the high doses of t-PA currently being tested can cause complications such as bleeding, more studies are needed to determine optimal—preferably lower—doses, he noted. Increased risk of bleeding can also be traced to the interaction of t-PA with heparin, another drug given to heart attack victims, Sobel said. Attempts are now being made to develop t-PA variants that may reduce such interactions, he said.

Another problem to be solved is that complications can develop when t-PA dissoves a clot, allowing blood to surge back into oxygen-starved heart muscle, Sobel said. Even a short period without oxygen, followed by a resurgence of blood flow, can damage heart tissues, Sobel said. Researchers are exploring the use of "calcium blocker" drugs in conjunction with t-PA to minimize some of these damaging effects, he added.

Sobel's presentation was one of six at the symposium entitled "Clinical applications of cloned gene products," a daylong meeting focusing on new drugs produced through genetic engineering techniques.

One of the handful of such recombinant-DNA derived products already available to patients is human growth hormone (HGH). Dr. Ron Rosenfeld, Stanford associate professor of pediatrics, discussed the benefits of HGH for children who are growth hormone-deficient and the ethical questions surrounding its other potential applications.

HGH has been available for many years but only last year did the Food and Drug Administration (FDA) approve the use of "recombinant" HGH obtained through genetic engineering techniques, Rosenfeld explained, after clinical studies at Stanford and elsewhere proved that it was effective and safe in inducing normal growth in HGH-deficient individuals. Over 1,000 such children have now been treated with good results, he said.

11-10-86

more

There may be some medical conditions in which patients can benefit from HGH even though they have normal levels of growth hormone, Rosenfeld said.

For example, he reviewed preliminary results of a Stanford study in which HGH was given to girls with a genetic abnormality called Turner's syndrome. Despite their ability to manufacture growth hormone, Turner's patients have abnormally short stature, he explained.

Although none of the Turner's patients receiving HGH has yet reached adulthood, over the short term those getting the drug have achieved increased growth rates, he said.

Growth hormone is being touted as a potential treatment for conditions ranging from wound healing to osteoporosis, but it has not yet been proven effective in any of these applications, Rosenfeld said.

But now that large quantities of the substance are available to anyone who can get a doctor's prescription for it, the potential for misuse has become a concern, he noted. "Already we are turning away dozens of families" who want the substance to help their normal, but short, children grow tall, Rosenfeld said. In addition, the drug is beginning to be used for bodybuilding in Europe and in the U.S., he said.

Concern over widespread use of the agent when it's not medically needed focuses on potential dangers associated with its administration, the most serious of which is the possibility of inducing a diabetes-like condition, Rosenfeld said.

A variety of substances produced by the body's white blood cells are undergoing clinical tests in cancer patients, and several speakers focused their presentations on early work with these agents. One of these cloned gene products, alpha-interferon, has already been approved for one specific use by the FDA, noted Dr. Jordan Gutterman, professor of medicine at the University of Texas and M.D. Anderson Hospital and Tumor Institute.

Alpha-interferon, a molecule that seems to inhibit growth of some viruses and cancers, provides a complete or partial remission of a rare form of cancer called hairy cell leukemia in approximately 90 percent of patients receiving the drug, Gutterman said.

"It isn't a cure," he noted, because many patients get a recurrence of the disease if they stop taking the drug. But so far, most hairy cell leukemia patients who continue the treatment are able to resume normal lives.

Gutterman and his colleagues are now testing alpha-interferon in patients with a blood cancer known as chronic myelogenous leukemia (CML). Preliminary results suggest that about 80 percent of patients who get the drug obtain remission of their disease, although it's too early in the study to draw conclusions, he cautioned.

A combination of alpha-interferon and a closely related compound, gamma-interferon, is also undergoing testing in CML patients, Gutterman noted, with early indications of a high response rate. But again, he cautioned that it is too early in the studies to draw conclusions.

Another potential anti-cancer agent under investigation is tumor necrosis factor (TNF). Clinical trials combining TNF and interferons are just getting under way, Gutterman said.

Although test-tube studies suggest that TNF has potent destructive effects on certain types of cancer cells, in the last year or so researchers became concerned about its potential side effects, primarily as a result of the discovery that TNF is identical to a substance known as cachectin, which causes the "wasting" away of the body seen in cancer and many other chronic diseases.

Dr. Anthony Cerami, professor of medical biochemistry and a dean at The Rockefeller University, led the studies proving that TNF and cachectin are one and the same. He reported on ongoing studies to further clarify exactly what role the TNF-cachectin molecule plays in the body.

Other speakers discussed hormones whose wide-ranging effects in the body are just beginning to be understood.

Dr. Charles Dinarello, associate professor of medicine and pediatrics at Tufts University School of Medicine, spoke about interleukin-1, a fever- and sleep-inducing protein that has many important functions in helping regulate the body's immune system.

Dr. Ferid Murad, Stanford professor and acting chairman in the department of medicine, reported on his laboratory's studies of atrial natriuretic factor, a newly discovered hormone made by the heart that some day may have potential for treating heart disease, high blood pressure and kidney failure.

All the speakers stressed the fact that basic scientific research has made possible the new treatment possibilites of these compounds.

"All of this progress depends on work that has been done in basic biochemistry and molecular biology," Sobel remarked.

A major thrust of Stanford Medical School's Program in Molecular and Genetic Medicine is to bring basic and clinical scientists together to shorten the lag between scientific discoveries and bedside medical applications.

KIDNEY TRANSPLANTS RESUME AT STANFORD

STANFORD—

Stanford University Medical Center, the West Coast pioneer in kidney transplants, will resume the procedure after a decade as part of a major thrust in transplantation medicine.

Dr. Stuart M. Flechner, associate professor of surgery and director of Stanford's renal transplant center, said the first transplants probably will take place this month. He said final approval for the procedures was received from the federal Health Care Financing Administration (HCFA) after a site visit Oct. 29.

That visit was necessary before HCFA could issue a license for transplantation, but Flechner described it as routine, "to verify the qualifications of the people and support services involved in the transplantation process."

Flechner came to Stanford in September from the University of Texas Medical School at Houston, which has one of the largest renal transplant programs in the United States.

Stanford will probably perform 15 to 30 transplants the first year, he said. "Our primary goal is to establish a first-class clinical program which will emphasize patient care and investigation into newer approaches which will enhance the chances of a successful transplant."

The first kidney transplant on the West Coast was done at Stanford in 1960. Dr. Roy Cohn, professor emeritus of surgery who headed the renal transplant program, said the first patient was Lenneth Pock, who received a kidney from his identical twin brother, Kenneth.

Cohn said the first 10 patients he operated on at Stanford all received kidneys from relatives. "We had much better control of rejection that way," he explained.

Eventually, surgeons were able to control rejection sufficiently to use kidneys from cadavers and more than 100 transplants were performed at Stanford before the program was phased out, initially because of the cost.

"We had a problem here with financing," Cohn said. "The (federal) government wouldn't finance the operations, and they were very expensive." Cohn said he suggested the late Dr. Samuel Kountz, who was performing the bulk of Stanford's transplants, move to the University of California-San Francisco, which was receiving financial aid from the state. At that point, Stanford's program stopped.

Federal financing now makes it feasible to restart the program as part of an expanded emphasis on transplantation at Stanford.

more

11-5-86

In addition, there is a growing need in the area for a kidney transplant center, Flechner said. He noted that Santa Clara County is the fastest-growing portion of the Bay Area and has "a large dialysis-based population" of people suffering from end stage renal disease (SRD), but there has been no hospital closer than San Francisco performing transplants.

Stanford's well-established reputation for innovation in immunosuppressive techniques to block the body's rejection of transplanted organs was one of the things that attracted Flechner to the Medical Center.

Flechner plans to investigate the possibilities for limiting immunosuppressive drug use in transplants. "My career interest," he said, "has been in looking at ways to immunosuppress patients without steroids and to look into steroid-sparing forms of immunosuppression. Many of the complications relating to transplantation have been due to chronic administration of steroids."

Although all drugs have some adverse side effects, the immunosuppressive drugs cyclosporine and prednisone have helped produce a dramatic increase in the success rate of kidney transplantation from cadavers, Flechner said. However, he added, kidneys donated by relatives have an even better success rate.

"Better than 9 out of 10 living-related kidneys are working two years after transplantation," he said, "and about 7 to 8 out of 10 kidneys from cadavers are working two years after transplantation."

The use of cyclosporine has permitted the successful transplantation of kidneys without extensive preconditioning of patients by blood transfusions or surgically removing the spleen. It permits living donor transplants to be done without the risks of sensitization, which is so frequently observed when donor-specific blood is used.

Flechner performed hundreds of transplants in Texas, including one on a 1-year-old boy who was the youngest kidney recipient in Texas. He was a co-investigator for the initial federal Food and Drug Administration-sponsored trials demonstrating the efficacy of cyclosporine in clinical kidney transplantation.

Before joining the University of Texas faculty in 1981, Flechner was a fellow in transplantation and renovascular surgery at the Cleveland Clinic Foundation. He received both his bachelor's degree and his M.D. from UCLA. He was an intern at UC San Francisco, where he also served a residency in surgery and urology. He also was a resident at the University of Liverpool, England.

SEARCH COMMITTEE FOR DERMATOLOGY CHAIR APPOINTED

STANFORD—

A search committee to recommend candidates for the vacant chair of the department of dermatology of the School of Medicine has been appointed by Vice President and Dean David Korn.

The eight-member committee will be chaired by Dr. Bruce Tune, professor of pediatrics.

The chair of dermatology has been vacant since Eugene M. Farber who headed the department for more than 30 years became professor emeritus. Dr. Paul Jacobs, professor of dermatology has been serving as acting chairman since 1985.

The committee, the dean said, should "seek the opinion of colleagues from inside and outside the school." During the past few months, the dean added, he had received advice about potential candidates during discussions with colleagues in academic dermatology and from an ad hoc advisory committee of full-time and voluntary faculty.

Dr. Robert W.P. Cutler, associate dean for faculty affairs, will continue to work with the ad hoc advisory committee as appropriate, Korn said. Marian Knox, assistant dean for faculty affairs, will coordinate the staff support.

The members are David Denneau, clinical associate professor of dermatology; Sarah Donaldson, associate professor of radiology; Leslie Dorfman, associate professor of neurology; Ronald Dorfman, professor of pathology; Stanley Falkow, professor of medical microbiology; Peter Gregory, professor of medicine (clinical) gastroenterology; and David Spiegel, associate professor of psychiatry.

BOOK DISSECTS HEALTH ECONOMY, NEW WAYS OF THINKING ABOUT IT

STANFORD—

Admirers and students of Victor R. Fuchs will be especially pleased to see the noted Stanford health economist's previously published thoughts and insights accommodated in a single volume.

The Health Economy, 401 pages. Harvard University Press, 1986, $25, however, manages to be more than that: the essays adhere to Fuchs as a narrator in a process that lends his book an autobiographical sensibility—a meditation on a topic he admits is "difficult and complex."

"An economist is a person who sees something that works in practice and wonders if it will work in theory," Fuchs raises a finger in warning. "My view is somewhat different. Once a problem or puzzle engages my attention, I may use economic theory as a starting point, but then usually move rapidly to an examination of data through statistical analysis and through observation and reflection on the behavior of individuals and institutions. Useful answers to the questions only emerge, if at all, from a close study of the particular phenomemon."

The collection of essays spans some 15 years of Fuchs' work as a Stanford professor of economics and research associate at the National Bureau of Economic Research. His essays reflect many aspects of the health care debate from a broad social, political and economic perspective.

In the opening chapters, Fuchs discusses the relevance of economics to health problems, starting with the time in which many were looking for "a technological fix" to improve the population's health and contain the cost.

"It seemed to me then (and seems now) that the emphasis on technology was overdone," he writes. "When I entered the field I found that medical research, education and practice were overwhelmingly concerned with the diagnosis and treatment of diseases, not with the preservation and enhancement of health.

"Health policy, not surprisingly, also emphasized medical care as the primary route to better health; the physical and psychosocial environments and personal lifestyle did not receive attention commensurate with their importance."

Some of Fuchs' writings have used economic theory as a framework, but other studies, he admits, were sparked by casual observations.

For instance, a study of the economics of surgery grew out of what he describes as "a back-of-the-envelope calculation." It showed the ratio of operations to surgeons in the United States to be surprisingly small, but the product of that ratio and the average fee per operation to be substantial.

Another notion examined by Fuchs and widely debated has been the extent to which the laws of supply and demand apply to medicine. Some economists have argued that use of medical care is decided by the patient, and that information about income, insurance coverage and price is sufficient to explain and predict changes in demand of physicians' services.

But Fuchs found the supply of physicians to be an important determinant. "Because physicians can and do determine the demand for their own services to a considerable extent, one should be wary of plans which assume that the cost of medical care would be reduced by increasing the supply of physicians," he warned.

Fuchs confesses that involvement in policy debates has not been high on his agenda. He hopes, however, some of his work to be relevant to policymakers. In his essay "From Bismarck to Woodcock," for example, Fuchs examines the popularity of national health insurance around the world. He concludes that such programs encourage people to overuse medical care, and from an economic point of view are irrational. But "there may be some welfare gains lying below the surface that more than offset the losses so apparent to economists," he notes.

As everyone familiar with medical institutions knows, the verb "to restructure" has become an important semantic figure to describe the revolutionary changes in the way both the government and the public pay their medical bills. The policies have been motivated by public concerns about the high costs of medical care in light of a slow economic growth. But change in itself is not always a supreme virtue and Fuchs is worried.

"Every revolution carries with it the seeds of its own destruction," he writes.

The problem he sees is excessive preoccupation with saving money. That is to be done by slowing down an overuse of medical services, eliminating questionable technologies and programs, and addressing the glut of specialists and surplus hospital beds.

In doing so, the revolution has created new problems, he notes. They include inadequate insurance coverage for millions, erosion of professional ethics as an instrument of control, battles over money and power between doctors and hospitals, loss of trust between patients and their doctors, and a decrease in useful services. Surprising, the battle for control of medicine is not between doctors and the government, but between doctors and managements of medical care institutions.

As to the outcome, Fuchs predicts that physicians will lose some power. "Control of medicine, as far as I can see, will never again belong completely to physicians."

The negative aspect of these developments is that they are occurring at a time in which the health problems of younger people are dominated by trauma, suicide, homicide and accidents coupled by an aging population consuming a significant amount of the health dollar.

But Fuchs is an optimist. He doesn't think people face more insidious problems or venture into more precarious areas than other men have done. Like the Chinese curse, "May God let you live in an interesting time!" he thinks our times are interesting.

"Scientific advances have extraordinary implications for medical practice, medical education and health policy," Fuchs writes. "For instance, the elucidation of the role of genetic factors in disease will compel much greater attention to populations, to statistics, and to epidemiology—not just for a few diseases, but over a broad spectrum of illnesses.

"Genetics may prove to be the key that brings together disparate elements of university medical centers into fruitful cooperative efforts."

The challenge Fuchs sees is how to capture and preserve the benefits of the revolution while minimizing its costs. "Now that society has decided it can call the tune, it must think carefully about what tune it wants the piper to play," he concludes.

FISH OIL SUPPLEMENTS NEED MORE TESTING, SAY STANFORD RESEARCHERS

STANFORD—

Fish oil food supplements will be scrutinized in a five-year study by Stanford researchers who say the recently touted product may be "too good to be true" in helping to prevent heart attacks.

The promising fish oil, packaged recently in capsule form, has been advertised heavily in recent months based on studies which show that Eskimos, who eat large quantities of cold water fish, tend to avoid heart attacks.

"OMEGA-3 fish oil may offer great promise in reducing cardiac risk and may even have benefits unrelated to heart disease," said Dr. D. Craig Miller, associate professor of cardiovascular surgery. "But the bottom line is that no one really knows for sure."

It's not that Miller and his colleagues are pessimistic. Preliminary pilot results in animal experiments at Stanford already have shown that EPA, a key ingredient in OMEGA-3, has retarded hardening of the arteries (arteriosclerosis) in vein grafts, Miller said. The studies involved the type of accelerated hardening of the arteries that occurs when a vein is grafted from one place in the body to another, such as in bypass surgery.

"A serious concern is that some of the recent claims, particularly from companies promoting products containing the oil, have been fantastic and need to be scrutinized. That's one reason why we're undertaking this multidisciplinary study to take a close look," said Miller, principal investigator in the study which will be supported by a $1.1 million grant from the National Institutes of Health.

The study was conceived by Dr. Peter Cahill, a cardiovascular surgery research fellow with a special interest in OMEGA-3.

Funding for the study was unusual. The Stanford group asked for three years of funding, but the NIH extended the protocol for two additional years. Most federal studies are approved at levels shorter or less costly than applied for.

"Funding of a longer, more costly study than we originally applied for is some indication that the government is anxious to see some meaningful scientific data regarding this controversial, but potentially valuable, health aid," Miller said.

The scientists plan to study the effects of OMEGA-3 on the biochemical, cellular and entire animal level. They'll be looking at the effects of the chemical on individual cells, on the arteries of animals given large doses of the substance, and eventually on the health of animals and human volunteers who will take large doses.

In addition to the potential cardiovascular benefits, Miller and Cahill and the team will also look at the possibility that the fish oil might benefit sufferers of arthritis or other so-called autoimmune diseases.

Television commercials are picturing healthy Eskimos in idyllic settings. The ads promise longer, healthier lives by taking tablets containing OMEGA-3 fatty-acid fish oil.

Here's what triggered the current interest:

A 1977 study of Greenland Eskimos has traced that group's low incidence of heart disease to consumption of large quantities of cold water fish, including salmon, mackerel, bluefish, herring and menhaden. Further studies showed that when Eskimos moved to Denmark and ate a Western diet, their cardiac risk went up.

The central ingredient which appears to be beneficial is eicosapentaenoic acid (EPA), said Miller, and that's the chemical which has been partially isolated and is now one of the active ingredients in OMEGA-3 tablets marketed under a variety of trade names.

The fish oil derivative can be sold without the extensive testing and approval normally reserved for medications, because it is a food derivative and as such doesn't require the same level of federal testing as drugs, Miller noted.

The capsules offer a concentrated form of the substance that could only be duplicated by eating a diet which is very high in fish. The tablets have also been processed to eliminate partially the "fishy" smell or taste.

Miller and his colleagues are optimistic but less than certain that the food supplements can significantly change an individual's risk of heart attack or slow down the underlying hardening of the arteries.

"There are a lot of unknowns. Some questions we need to answer include, first and foremost, whether the EPA is in fact the ingredient which is beneficial. Secondly, even if the ingredient is useful, what dose is useful or optimal? Will it work in everyone?

"Is it equally effective in processed form? What are the mechanisms responsible for its effects? Is it effective when added to a Western diet, or has it worked for the Eskimos in combination with the other food they eat? Are there any side effects which could be potentially deleterious?" Miller asked.

One side effect has already been noted among the Eskimos. The EPA appears to allow them to bruise more easily, because the platelets in their blood are less sticky than in most Europeans. The effect appears to be relatively harmless, and the finding is further evidence of EPA's benefit, since it suggests that the diet is altering the platelets, which is the component of blood associated with normal clotting.

EPA's ability to make blood platelets less sticky may be a key to its potential effectiveness, and that is one primary area Miller and his colleagues will be exploring. Less sticky blood platelets tend to resist clotting and clogging key points in the artery.

EPA, said Miller, may lower cholesterol and almost always lowers high levels of triglyceride in the blood. Both of these substances have been associated with heart disease.

The EPA appears to reduce inflammation in autoimmune diseases such as arthritis, psoriasis or lupus, by interacting with compounds in the blood called leukotrines, chemical messengers which promote inflammation.

Again, further study is needed.

The use of EPA isn't new. In fact many people's grandparents have told them to use it. It is found in cod liver oil. However, cod liver oil is not the best source, since it also contains large amounts of vitamin A and D, which in doses large enough potentially to reduce heart attack risk could be toxic, researchers explain.

The study was conceived by Cahill, who has a particular interest in OMEGA-3," Miller said.

Joining Miller and Cahill in this study are Drs. Allen D. Cooper, associate professor of medicine (gastreoenterology); Frederic B. Kraemer, assistant professor of medicine (endocrinology); Jon C. Kosek, professor of pathology; R. Scott Mitchell, assistant professor of cardiovascular surgery; Randall E. Morris, a cardiovascular surgery senior research associate who will study the immunological aspects of EPA; and Peter D. Wood, research professor of medicine and associate director of the Stanford Center for Research in Disease Prevention.

5-MONTH-OLD INFANT IN STABLE CONDITION AFTER HEART TRANSPLANT AT STANFORD

STANFORD—

A 5-month-old male infant, Stanford University Medical Center's youngest heart recipient, was reported in critical but stable condition Wednesday and had been taken off the respirator originally needed to assist his breathing.

The infant received his new heart Tuesday after a dramatic cross-country flight by a North Dakota National Guard F-4 jet carrying the donor organ strapped in the back seat.

Dr. Norman E. Shumway, chairman of the Department of Cardiovascular Surgery, and Dr. Vaughn Starnes, chief resident in cardiac transplantation, performed the operation 7 ½ hours after the heart was taken from the donor body.

Both took particular note of that time. Shumway said it was the longest a donor heart had been out of a body and successfully transplanted and Starnes said "the real significance" of the operation was the fact that the out-of-body time for the heart had been extended "to nearly twice what we considered (reasonable)."

The recipient and donor families both requested anonymity. The recipient suffered from endocardial fibroelastosis, a disease characterized by a thickened endocardium, which interferes with heart function.

North Dakota's governor, George A. Sinner, and the National Guard became involved when a Stanford medical team was stranded on the ground in Fargo after picking up the heart. The leased Lear jet flown to Fargo developed trouble and could not get airborne.

At that point, Dr. Edward Stinson, professor of cardiovascular surgery heading the Stanford team, called Sinner.

Sinner received the call at 2:30 a.m. CST and immediately alerted the National Guard. "The plane was in the air within 30 minutes," he said. "The guard is less than a quarter of a mile from the private terminal where the Lear jet was."

The F-4 is a two-seat supersonic plane, but Sinner said the pilot, Lt. Robert Becklund, had to make the flight solo "because the container with the heart was strapped in the back seat."

Becklund made a refueling stop in Ogden, Utah, then flew to Moffett Field Naval Air Station in Mountain View, from where the heart was rushed to Stanford.

The total flight time was three hours and the heart had been out of the donor's body 7 ½ hours by the time the operation started at 4:30 a.m. PST. Shumway said that despite that record time, the operation went very well. He added that one reason Stinson went to North Dakota to pick up the heart was because the expected delay in transplantation made evaluation of the organ critical.

12-24-86

more

Shumway said, "If Ed (Stinson) hadn't been there to evaluate the heart, we would not have done the transplant."

Marguerite Brown, transplant donor coordinator who accompanied Stinson to Fargo, noted that four hours is the comfortable length of time for a donor organ to be out of the body without losing any of its ability to function.

Fargo was pushing the outer limit of time for getting donor organs, Brown said. "But pediatric hearts are so rare we thought it was unlikely that another one would become available in time to help this baby."

Brown said she, Stinson and four other transplant team members left the Bay Area at about 2:30 p.m. Monday and landed in Fargo three hours later. She said the donor heart was ready for transport by 8 p.m. PST, but on the runway the left engine of the Lear jet failed.

Mechanics were unable to get it started, and after consultation with a National Guard colonel in charge of the base, Stinson decided to call the governor and ask for his help. Stinson also was crucial in negotiating transport issues with the National Guard, Shumway said.

Sinner said that when he was awakened at 2:30 a.m., he expected the worse because "when a governor gets awakened at 2:30, it's usually something bad. I was glad it was something I could actually do something about."

Stinson, Brown and other members of the transplant team returned to the Bay Area via commercial airliner later in the day. Brown said that she had made about 150 flights to pick up donor organs, "and this was the first time the plane wouldn't start."

Shumway, who performed the first heart transplant in the United States, has long advocated transplants in younger patients. Last summer, Stanford announced plans to perform transplants in neonates—infants in the first 6 to 8 weeks of life—as soon as suitable transplant candidates and donor organs were available.

Starnes presented a paper at an American Heart Association meeting in Dallas last month stressing the encouraging results of heart transplants in children and adolescents at Stanford. Asked Tuesday about the ethical considerations involved in heart transplantation for infants, he said, "Without it, there is no hope; with it, there is optimism."

The infant transplanted Tuesday was Stanford's youngest by more than two years. The previous youngest was Elizabeth Craze, who was 2 ½ years old when she received her heart in October, 1984. Caillie Stufflebeam, 4 ½-year-old from Seaside who received a heart Sept. 15 and a second one Thanksgiving Day, is still recovering in the hospital.

BRAIN CHEMICAL MAY BE LINKED TO EXTROVERTED PERSONALITY

STANFORD—

Extroverts — outgoing, active and talkative people — may have higher levels of the brain chemical dopamine than more introverted people, suggests a new Stanford University Medical School study.

It appears to be the first research finding that links one of the brain's chemical messengers to a general personality trait, said Dr. Roy King, assistant professor of psychiatry and behavioral sciences.

King cautioned that the research represents just a first clue to understanding the neurochemistry behind the many variations of human personality. The findings could also contribute to a better understanding of the chemical basis of behavioral problems such as drug addiction and social withdrawal, he added.

The findings are published in the December issue of *Psychiatry Research* by King and his colleagues Dr. Ivan Mefford of the National Institutes of Mental Health, Stanford research assistants Clifford Wang and Allison Murchison, Boston College graduate student Edward Caligari, and Dr. Philip Berger, Norris professor of psychiatry and behavioral sciences at Stanford.

The research was funded by grants from the Robert Wood Johnson Foundation, the MacArthur Foundation and the National Institute of Mental Health.

In the last decade, scientists have begun to explore potential links between brain chemistry and psychiatric disturbances such as depression, anxiety and schizophrenia, but few studies have probed the connections between brain chemistry and normal personality traits, King explained.

Instead of studying how the brain's chemical messengers regulate despair, King and his colleagues set out to learn how brain chemicals regulate positive types of behavior, such as extroversion or reward-seeking.

Animal studies had already suggested that in certain brain regions the chemical messenger, dopamine, may help regulate reward-seeking behavior, such as excitement when a hungry animal seeks food, King explained. The brain areas involved are the frontal cortex, the medial caudate, and the base of the brain in the temporal lobes, he said.

The scientists hypothesized that dopamine activity in similar brain regions might underlie human extroversion since the excited and energetic activity of an extrovert in many ways resembles reward-seeking behavior in animals.

In the study, the researchers compared dopamine concentrations in cerebrospinal fluid samples from individuals who had completed the Eysenck Personality Inventory, a psychological test that distinguishes extroverts from introverts. Cerebrospinal fluid (CSF) is the liquid that bathes the brain. CSF dopamine levels are thought to reflect levels of dopamine activity in the brain regions that interested King and his colleagues.

The study subjects were 16 male patients whose CSF had been obtained for a depression-related neurochemical study. None was taking anti-depressant drugs at the time the samples were obtained.

They found significantly higher levels of dopamine in cerebrospinal fluid of the more extroverted patients, King said.

Since the study was carried out in a group of people diagnosed with depression, the researchers are not sure how far the results can be generalized. But because they found no correlation between intensity of depression and dopamine levels, "we think the dopamine concentrations reflect something deeper, such as a basic personality trait" King said. The next step in their research is to examine CSF dopamine levels in non-depressed people.

For years, scientist have debated whether an individual's temperment is molded more by environment or by heredity. Studies of twins and other evidence suggest that an extroverted personality can be inherited, King said. "This new finding may be another step towards trying to resolve the 'nature versus nurture' debate," he added.

The new information also could help explain how certain drugs create their "highs," King said, and might be a new lead in studying drug addiction. Substances such as cocaine and amphetamines cause a release of dopamine in these same parts of the brain, he noted. "The reward of a drug high is an important motivating factor in humans as well as in animals, and may underlie substance abuse," King explained.

The new information might also shed light on personality disorders such as social withdrawal, the opposite of extroversion, or anhedonia, a condition in which people cannot experience pleasure or reward, he said.

CHILDREN'S HOSPITAL AND NURSES BOTH FIND RELIEF IN FLEXIBLE SCHEDULING POLICIES

STANFORD—

For nine months each year, Nancy Dinsmore of Palo Alto cares for young cancer patients at Children's Hospital at Stanford. Then she packs her bags and boards a cruise ship headed for Alaska, the Caribbean, or Tahiti.

Dinsmore is one of many Children's Hospital nurses who have arranged their jobs to suit their individual needs. One of her colleagues continues her medical career while solo-parenting two young children. Another pursues a master's degree without giving up her charge nurse position.

Altogether, about 90 percent of Children's Hospital nurses have designed something other than a regular 40-hour work week.

These nurses help Children's Hospital at Stanford maintain high staffing standards in the midst of a national nursing shortage. In return, Children's Hospital helps them fit together the sometimes irregular pieces of a modern lifestyle: family demands; professional requirements; personal needs for decompression, variety, and even adventure.

To assist qualified nurses in solving their individual lifestyle puzzles, Children's Hospital has designed a set of flexible policies and programs, including:

- A relief pool system that allows nurses to work as few as 20 and as many as 40 hours a week, at times of their own choosing.
- Job-sharing arrangements that enable two nurses to share one position.
- A liberal benefits policy that provides full benefits starting from day one on the job, even for employees working less then full time.

The relief pool system is particularly attractive to nurses who have returned to school and to young mothers who cannot work full time but need to maintain full benefits.

"It's a matter of moving pieces here and there," says Carol Bradshaw, director of nursing, who helped develop the plan. The relief pool approach has helped Children's Hospital avoid expensive solutions to the nursing shortage, such as high-priced personnel agencies, costly recruiting campaigns, and cash incentives for signing contracts.

Bradshaw understands the many personal and professional pressures felt by her nursing staff. She earned her own advanced degree, subject by subject, at night and on weekends, while working full time.

"Most times the system is loaded on the hospital side," Bradshaw observed. "That's short-sightedness on the part of hospital administrators. Here we try to treat our nurses like customers. We make them feel it's worth their while to work with us, that it's something they want to do, not something they've got to do. The key is to keep that delicate balance between our needs and their needs.

"The relief pool works also wonderfully when a husband says to his wife, 'I have two weeks off, let's go to Hawaii,' and she can say, 'Sure, let's go!' " Bradshaw said. The pool then furnishes someone to cover for her.

Children's Hospital maintains a roster of approximately 200 trained nurses, 25 percent of whom work part time. Many work only weekends or evenings in order to make room for other commitments.

An enthusiast for the program is Kris Jessen, who has worked full time at Children's Hospital for 11 years.

"I never thought I'd stay this long," Jessen recalled. "I like it here because I get involved with my patients and with their whole family. The other day, a 4-year-old patient said to me: 'When I grow up I'd like to be a nurse.' It's that sort of thing that keeps us here."

Jessen decided recently to go back to school for a master's in pediatric nursing. To make time for studies and continue working at Children's, she now shares her job with Miriam Powell, who herself cannot take a full-time position because she has a young child at home.

Nancy Dinsmore, who cares for critically ill children in the Auxiliary Unit, balances her stressful duties with three months as a cruise ship nurse each year.

"I take care of all nursing needs on board, which means anything from band-aids to resuscitating a heart attack victim," Dinsmore said. "The crew comes from many different countries, so I can practice cross-cultural nursing, which I find quite stimulating."

While she enjoys life at sea, Dinsmore also values her work at Children's. By contracting to work 40-hour weeks for nine months, she has three months each year to explore exotic destinations.

Under the relief pool system, nurses sign a monthly commitment, agreeing to the number of hours they will work and dates when they will be available. It falls on Michael Puff, a full-time staffing person, to match the nurses' schedules against the hospital's needs. The complicated computerized system may leave Puff with as many as 21 vacancies to fill in a given day.

On those occasions, Puff has to be very persuasive. "If you know your nurses well and understand that they're individuals with their own individual concerns, the job becomes easier," Puff said.

"On holidays when I schedule the shifts a month ahead, I know precisely who is visiting a grandmother, who has a sick child that day, who has a cousin visiting and who is baking the turkey this year. And who might be available."

Children's Hospital demands highly skilled nurses because the institution cares for children during acute episodes of such long-term, catastrophic diseases as cancer and cystic fibrosis. Nursing these children is stressful and produces a high rate of burnout, according to Bradshaw. In addition, Children's requires expert nursing around the clock and on weekends, including time slots that are traditionally difficult to fill.

With this in mind, Bradshaw has a set up a rotation system in which nurses in high-stress positions are assigned to the outpatient clinics for two-month tours. The program provides relief from difficult environments and allows nurses to follow patients after they have recovered from acute episodes. "For many nurses, this gives their jobs more meaning. That is important in our line of work," Bradshaw said.

To help fill weekend slots, Children's offers bonuses. In addition to their regular salaries, nurses who have worked 48 extra weekend hours over a period of time receive an extra $5 per hour, retroactively. "That means a lump sum of $240, which can come in handy when they want to buy something special or when tax time comes around," Bradshaw noted.

CHILDREN'S HOSPITAL HELPS OBESE CHILDREN GROW TOWARD NORMAL WEIGHT

STANFORD—

Twelve ounces does not sound like a lot of weight. For a group of obese children who participated in a Children's Hospital at Stanford study, however, two-thirds of a pound represented a major victory.

Obese children have a different problem than obese adults. Their goal is to grow, but to lose weight relative to height. The yardstick for measuring success is the Body Mass Index (BMI), which is calculated by dividing weight by the square of the height.

For 10 youngsters involved in the Children's Hospital pediatric obesity study, the overall BMI for the group declined from 23.85 to 22.95, or approximately 5 percent, over a 10-week period. On the average, each child lost two-thirds of a pound while growing about three-quarters of an inch.

Mothers who participated in the program also lost weight, about 2.5 pounds apiece. Researchers theorize that this reflects parents' better understanding of nutritional principles and a generally better "food environment" in the home.

That is a problem for many American children. Approximately 15 percent of all U.S. youngsters are clinically obese. Studies have demonstrated that obese children are likely to become obese adults. A long-term weight problem poses life-threatening medical risks.

"Clinical obesity is associated with physiological complications, such as high blood pressure and diabetes, as well as psychological disorders, including low self-esteem and depression," explained Dr. Lawrence D. Hammer, director of the pilot program.

But improper attempts to lose weight can be just as dangerous as obesity.

"Children must have adequate nutrition in order to develop normally. Uncontrolled dieting can actually retard growth," continued Hammer, assistant professor of pediatrics at Stanford University School of Medicine. "Parents should be very cautious about putting young children on diets without adequate supervision."

Hammer and his colleagues believe that by intervening early they can help children learn new attitudes and behavior patterns that will be carried into adulthood. Their pilot treatment program is aimed at building healthy eating patterns, encouraging selection of more nutritious foods, and increasing physical activity.

The treatment team, which includes Dr. Robert L. Berkowitz, clinical assistant professor of psychiatry, and research assistant Ronda Flanzbaum, has focused initially on overweight children between the ages of 4 and 6. Their program is designed to influence the eating patterns of the whole family. For each child, at least one parent must participate in 12 weekly sessions.

Of 10 children who participated in the first pilot program, nine completed the course. Participants in the program were generally more than 20 percent above their ideal body weights and eight of the nine finishers were among the top 5 percent of their age group in terms of body mass index.

The Children's Hospital program utilized the "Traffic Light Diet," developed at the University of Pittsburgh. The Traffic Light system divides foods into three groups based on nutritional value relative to calories.

Nutritious, low-calorie foods such as fresh fruits and vegetables get a "green light," meaning that you can eat all you want. Red light foods, such as cake, candy, and pizza, should be reserved for special occasions. The yellow light category should be consumed with caution.

Therapists used games and flash cards to help children distinguish between food groups. The youngsters also exercised for 15 minutes during each hour-long meeting.

"They need to learn what it feels like to have their hearts beat fast, to work up a sweat, and to get tired," Hammer explained.

Meanwhile, the parents learned to encourage correct eating habits and daily physical activity in their youngsters, and to control the foods made available to their children at home. The group sessions also allowed the parents to discuss the difficulties they experienced.

The parents helped their children keep daily records of the foods they ate. Children who achieved their dietary goals were rewarded with stickers and praise.

According to Hammer, the Traffic Light Diet may sound simple but it is not easy.

"It's almost impossible to go to a fast food restaurant and stay within the dietary recommendations," he pointed out. "Practically the only thing they could have would be plain hamburgers."

Hammer and his colleagues plan to organize a second pilot program in the near future. Children's Hospital also offers individual evaluation and treatment programs for overweight children and teenagers.

Funding for the pilot program has been provided by the multidisciplinary Stanford Center for the Study of Youth Development.

PLASTIC MAN LEAPS LEGAL BARRIER TO AID CHILDREN'S HOSPITAL VIDEO NETWORK

STANFORD—

When an innovative closed circuit television system for hospitalized children ran into legal problems, producer/director Steve Whiting sent a superhero to the rescue.

The legendary Plastic Man himself bounded into Children's Hospital at Stanford with 30 half-hour episodes of the *Plastic Man Comedy Adventure Show*, complete with public performance rights.

For children confined to hospital beds, television provides much-needed escape from the routines of treatment and recovery. Video also offers important educational benefits. With these possibilities in mind, Children's Hospital recently installed a closed circuit TV network.

The idea is to provide suitable programming, free of charge, at each bedside. By carefully screening the shows, Children's Hospital plans to avoid problems associated with some over-the-air broadcasts.

"Television can affect the psychosocial health of children," explained Family Health Education Library coordinator Suzanne Flint, who has led the television project. "It may influence their physical health as well."

Because sick children watch television at odd hours, they may be exposed to almost anything that is broadcast. "The majority of what they see is developmentally inappropriate," Flint observed.

Unfortunately, the closed circuit system ran into a legal roadblock. Most video programs and movies are protected by copyright laws. Copyright owners must give (or sell) permission whenever these materials are shown in public places, including hospitals. The entertainment industry is working hard to preserve this protection, and has already threatened to sue one children's hospital for showing videotapes to patients.

Public performance permits can be very expensive, even for nonprofit organizations like Children's Hospital at Stanford. One distributor is asking $3,500 annually plus videotape rental charges.

That's where Plastic Man comes in. Steve Whiting, who is based in nearby Woodside, Calif., heard about the video predicament at Children's Hospital when he volunteered to help out with a telethon early last summer. Whiting's Plastic Man show, which features gentle, tongue-in-cheek humor and zany cartoons, is just the kind of upbeat fare that children need. Young viewers have responded to Plastic Man's off-the-wall antics by keeping the show among the top four nationally syndicated children's programs.

Several months later, Whiting and San Francisco comic Mark Taylor (the flexible genius behind Plastic Man) brought a bundle of videotapes to Children's. They were received with enthusiasm by a group of patients, who were particularly impressed by Plastic Man's dark goggles and panty hose.

"If laughter is truly a powerful medicine, we hope these shows will make the stays of your young patients both cheerier and shorter," Whiting commented.

Whiting expressed hope that other producers will follow in his footsteps by donating programs to Children's Hospital. "Certainly we can find a way to protect the legal health of our industry and still bring some joy into the lives of these children," he said.

FREE SKIN CANCER SCREENING OFFERED BY STANFORD CLINIC

STANFORD—

Free screening for skin cancer will be offered Saturday, Jan. 10, at the Dermatology Clinic in the Stanford University Medical Center.

Dr. Chung-Hong Hu, director of the Dermatology Clinic and associate professor of dermatology in the School of Medicine, said the screening will consist of preliminary examination of the skin and is not considered complete diagnosis. Individuals with moles or other skin conditions that look suspicious will be advised to have more thorough examinations, including biopsies.

The examinations will take about 15 minutes, Hu said, and people will be examined in the order in which they arrive at the clinic. There will be no need to make appointments. Individuals who want inspections only of specific areas on their faces or extremities will not need to disrobe, but those who do disrobe will get more complete examinations.

Hu noted that skin cancer has been increasing rapidly in recent years, particularly among fair-skinned people who get sunburned readily. There have been estimates that 40 million Americans will develop skin cancer in the next century, and 400,000 will die from the disease.

Scientists have speculated that one reason for the increase in skin cancer is a thinning of the ozone layer in the upper atmosphere, which allows more ultraviolet light from the sun to reach the earth's surface. Another reason is increased recreational exposure to the sun.

But along with the increased danger of skin cancer, Hu said, there has been an increased awareness of the disease. The screening day is part of a campaign to educate the public further about the dangers and treatment, he said.

"If skin cancer is detected early, it can usually be treated easily," he said, and with early detection the cure rate is excellent.

There will be a full staff of six faculty members as well as residents and nurses on hand for the screening, which will be offered from 10 a.m. to 4 p.m.

The clinic, on the second floor of the Boswell Building, is accessible through the main entrance of the Medical Center. The location will be clearly marked by signs.

AZT AND OTHER DRUG TRIALS TO BEGIN IN AIDS PATIENTS

STANFORD—

Stanford Medical School researchers plan to begin two studies of the experimental drug AZT (azidothymidine) in AIDS patients beginning in January.

One study will test AZT's effects in AIDS patients with Kaposi's sarcoma, a malignant form of skin cancer. The other will test the drug's effects in patients who have had pneumocystis carinii pneumonia, a frequent complication of AIDS.

Both trials are part of a $100 million federally funded program, announced last June, to find a drug treatment for AIDS. Stanford is one of 14 medical centers nationwide participating in the program.

AZT is an experimental drug that has shown some promise in treating AIDS, although it is not a cure for the disease. In September, federal officials announced that the drug would be made available to certain types of AIDS patients, after preliminary results of a clinical trial suggested that the drug could prolong life.

But continuing studies are needed to accurately assess the drug's effects and to pinpoint the kinds of AIDS patients for whom it is most beneficial, explained Dr. Thomas Merigan, Becker professor of medicine and principal project investigator at Stanford.

Other experimental treatments for AIDS and ARC (AIDS-related complex) are also under way at Stanford, Merigan pointed out. Among the drugs under investigation are:

- Rifabutin, a potential agent for treating ARC;
- DHPG (di-hydroxy-propoxymethyl-guanine) and beta-interferon, two experimental drugs that may help control cytomegalovirus (CMV) retinitis, a viral infection commonly afflicting AIDS patients;
- Fluconazole, a new anti-fungal drug that may be useful in treating cryptococcal meningitis, a fungal infection.

Other studies may begin in coming months, Merigan added. Since each trial involves a specific sub-group of AIDS patients, potential volunteers must meet specific criteria, he noted. For more information, patients or their physicians may contact the Division of Infectious Diseases at Stanford University Medical Center or call (415) 723-6231.

PALO ALTO PHYSICIAN TESTS MEDICAL PRACTICE OF THE FUTURE

STANFORD—

Dr. Andrew Newman doesn't pretend to be clairvoyant, but he has a pretty good idea of what the practice of medicine will be like in the year 2000—he's already practicing medicine that way in his office at 1101 Welch Road, Palo Alto.

Newman can do his part in admitting patients to the hospital or having them discharged without leaving his office. He can also find out the precise status of all of his patients in Stanford University Hospital, including the types and amounts of medication they have received in the past few hours and whether they've been moved to a different bed during the night. Soon, he'll be able to get the results of laboratory tests just as easily.

The secret is Newman's computer, and the fact that he's hooked up to the SUH medical information system. That gives him instant access to all of the hospital records on his patients. That information could take hours, or even days, to track down through the usual methods of leafing through written records.

Newman is the only doctor outside the hospital hooked up that way now, but within a year or 18 months, there will be others. And in a few years, all of the physicians in a 20-mile radius could have the same direct connection to the hospital. It will be possible for a physician in Modesto—or in Calcutta, for that matter—to check the progress of a patient in Stanford Hospital almost as thoroughly as if the physician were on the scene.

A few hospitals around the nation have pilot programs linking physicians with certain specialties to the hospitals' information systems. For example, "a couple of hospitals in New York have tied all their obstetricians to this kind of program," Newman said.

But no hospital has attempted anything on the scale Stanford envisions. "My office is a prototype," Newman said. "Once the system is up and running we're going to try to have every single physician in town get some type of computer and hook into the system."

Those who do will enormously simplify their own record-keeping and their dealings with hospital records, Newman said. A physician will have all the medical information on a patient, plus all the necessary insurance information and data on Medicare or MediCal, all available within seconds on the computer screen.

When the patient is discharged from the hospital, all the information on medication that was administered in the hospital and given to the patient on discharge will be readily available to the physician. Newman pointed out that patients often don't remember information on medication and physicians can be tied up for hours getting it from the hospital.

Besides all the advantages of instant information, Newman said, "there are other tremendous benefits" provided by computers.

12/17/86

more

One such benefit will be the ability to tap into the National Library of Medicine and get information in minutes that would require hours of painstaking research in a printed library.

To show how that service works, Newman decided to check on all references in the national library to hyperbaric oxygen therapy that have been published since 1980. He found 1,354 references to hyperbaric, 33,748 to oxygen and 306,393 to therapy--but only 355 to all three words, hyperbaric oxygen therapy.

It's easy to break those references down even further, he noted, by searching through titles. Then a magazine article or professional document can be called up on the computer screen to provide detailed and specific information.

Another spinoff benefit of computerized medicine is what Newman calls the "business aspect." Instead of having someone spend half an hour on the telephone trying to track down insurance information on a patient for billing, as happens frequently now, physicians will be able to look at the hospital data base and find all the relevant information in about one minute.

There are other bits of information that will help immensely in dealing with patients. Newman explained:

"You've entered the data in the office after you see the patient and you can have that information on the screen when anybody calls up.

"So when you get on the phone with Jonathon Jober, instead of having him say, 'Are you sure you know who I am?', you know that he was born on this date in this state and this was his medical history. He had surgery, these allergies, he's a cigarette smoker, a mild wine consumer.

"You can also refresh your memory about important work or family details. It makes for radically better patient rapport."

Still another benefit is ready access to reference material the hospital has on line, such as poison control information. "If someone swallows a bottle of pills and you need to know what's in those pills, you can get that information right away," Newman said.

All of those things are available right now, but what really excites Newman are the developments still to come.

Among those are projects planned by artificial intelligence researchers at Stanford to teach computers to think like people. Newman described how that would work:

"The computer reminds you that you just gave blood pressure pills to a patient but you forgot that he also has gout and 20 percent of the time that blood pressure pill causes an exacerbation of the gout.... It doesn't tell you what to do. It doesn't make specific recommendations. It just gives a few helpful hints that you might have overlooked."

In another example, Newman said the computer might point out that "Mrs. Smith hasn't had a pelvic examination for nine years and she's of a risk group that the American College of Physicians would think should have it every two years."

Newman also expects personal computers to be used soon with compact disks, which can contain the equivalent of thousands of pages of information. Physicians would be able to keep what amounts to an entire encyclopedia set on one disk, calling up specific information in a few seconds.

more

With all of the advantages that computers will be able to provide, Newman thinks any physician would be foolish not to have one.

That's particularly true when the cost is considered, he says. "I'm not talking about millions of dollars in investments. I could put a system that did all this in your office for $2,000."

Getting physicians to plug into the Stanford Hospital system will come as soon as the system is completed, in a year to 18 months. The uncertainty is because the system is being custom designed by the Integrated Health Care Laboratory Technologies. That means it may take longer to install, but will be capable of modification whenever the hospital wants changes in the operation.

Stanford considers the system as a model that it hopes will be in widespread use at other medical institutions in the future.

The system will make it possible for people to carry small cards with all their basic medical information. Those cards can be put into computers at hospitals around the country and will provide major medical diagnoses, pictures of chest X-rays, electrocardiograms, etc.

Newman has been interested in computers ever since he went to Stuyvesant High School for Sciences in New York City and began working with the school's IBM mainframe computer.

When he came to Stanford, he said, "I got very interested in medical records. I found they were terrible by and large; nobody could read what anybody else wrote and you could never find the charts."

He became chairman of the hospital's medical records committee and as computer companies gan developing cheap, easy-to-use hardware he began testing ways of using computers to simplify record-keeping. He has been working with hospital administrators for about three years on the computer system.

Newman is excited about seeing the end of the project draw near because "it's one of the areas in which you can change the future. It will change how medicine will be practiced in my lifetime."

STANFORD NURSES SPREAD HOLIDAY CHEER

STANFORD—

The nurses in Stanford University Hospital's labor and delivery unit have been making lots of deliveries this month, but they haven't all been new babies.

With money they've raised among themselves, the physicians and other staff on the unit, they've been able to buy holiday food, clothing and other gifts for needy families in the Bay Area.

"This year we raised more money than ever before," said Gwen Anderson, who organizes the effort each year. With $1,500 they collected they were able to buy gifts--mostly warm clothing and food--for six predesignated families, as well as additional food and some holiday items such as cologne for many other recipients.

"Everyone just pulls together and we have such a good time buying, wrapping and delivering the gifts," Anderson says. "The feedback we get is really rewarding."

The charity started several years ago when the nurses decided to give presents to some truly needy people instead of to their colleagues on the unit. They contacted the Homemaker's Agency in Santa Clara County, who in the years since has identified families to receive the nurses' gifts.

Anderson said they also take the flower baskets left on the unit and fill them with flowers to deliver. This year, they were even able to purchase a movie screen for a nursing home.

RECOVERING ALCOHOLICS COMPARE CHRISTMASES PAST AND PRESENT

STANFORD—

Roger is really looking forward to Christmas this year—he's even enjoying pushing through crowds and standing in line while Christmas shopping, activities most people find too stressful to enjoy.

But Roger is savoring everything associated with the holidays because this is the first time in years that he hasn't stumbled through the Christmas season in an alcoholic fog.

Roger is one of a group of about 20 recovering alcoholics and/thor drug users who meet regularly in group therapy sessions organized by the Stanford Alcohol and Drug Treatment Center. One night last week they talked about the reality of this year's holidays compared with the hazy remembrances of those gone by. (Roger's name and those of all the group members have been changed.)

"I was always shortchanging my family," said Dave. "I always wanted to be away from my family and be with friends, drinking and using. When I was with my family, I was hung over and I'd cut the time short to get out with my friends. I felt tension and guilt when I was with my family."

Alcohol and drugs serve many psychological functions," explained Dr. Robert Matano, director of the Stanford program, "but at some point a new dynamic in the experience of addiction occurs. Seeking and obtaining the drug of choice becomes the individual's overarching purpose in life. All else becomes less important—family, friends, health—until a point of collapse and despair is reached."

Now that he's quit drinking, Dave is finding real joy and relaxation with his family, but that's not always the case with recovering alcoholics. Susan, for example, will avoid spending Christmas with her family this year.

"I come from an alcoholic family," she explained. "This is the first year in my life that I'm not going to spend Christmas with my family. It's not that I'm terrified they'll start me drinking again, but the gap between us is too big. It will be nice to have Christmas with my own friends."

"For many adult children of alcoholics who are also recovering alcoholics themselves, we have several obstacles in the recovery process," Matano said. "The individual is between a rock and a hard place: Having to give up alcohol sometimes means giving up close contact with his or her family. The recovery group often serves to satisfy familial needs and is particularly useful during time of stress such as holidays, when individuals feel the conflict acutely."

12-16-86

Just sitting down to a holiday meal has particular meaning for John.

"I was a cocaine addict," he said, "and cocaine takes away your appetite. I didn't feel hungry at all and I had to force myself to eat those big dinners. Then I'd go hide in the bathroom (to take cocaine). I really enjoyed Thanksgiving dinner this year. It was the first time I'd enjoyed a big dinner like that in a long time."

Matano explained that "when a person begins recovery and gives up drugs, he or she often experiences joys we take for granted, such as a return of appetite and normal sleep. Some people say it's like being a kid again, with all the joys of childhood."

Joan, a long-standing member of the recovery group, says the difference between sober and drunken holidays is that of real vs. imitation happiness.

"I enjoy them, and I never did before," she said. "I pretended to enjoy them, and certainly drank enough. Everybody would think: 'She's having a great time.' But I used to wish they'd take from Thanksgiving to Jan. 3 out of the calendar."

Most of the therapy group members are confident they can resist the pressure to drink during the holidays, but they know there will be more pressure than usual.

"There's an emphasis on celebration at this time of the year," Susan said. "You just have to keep your life simple and uncomplicated; remember what's important to you."

Roger pointed out that help is only a phone call away. "I have a book of numbers to call, of people in the program," he said. "They're available on 24-hour call to help me (keep from drinking) if it's necessary."

Joan had some practical advice: "I recommend carrying a six-pack of soda whenever you go to a party. People don't think; at a party they'll have wine, beer and mixed drinks and no soft drinks at all. Take something with you and don't trust to chance."

"The holiday season serves to accentuate both everyday and longstanding conflicts for individuals such as our patients have described," Matano said. "We stress in our program resolving individual and family issues that have prevented our patients from enjoying previous holiday seasons and to encourage them to participate in a recovery process that is like a state of childhood in which every day is a joy."

FIRST KIDNEY TRANSPLANT PERFORMED IN REACTIVATED STANFORD PROGRAM

STANFORD—

A young woman from Fairbanks, Alaska, received a kidney from her mother Monday in the first operation at Stanford University Medical Center's reactivated renal transplant center.

The daughter, Trudy Ekalook, 25, and her mother, Sharleen Ritchey, 43, of Livermore, Calif., both were "doing fine," according to Peggy Deveney, registered nurse who is clinical specialist for the renal transplant program.

The operation was performed by Dr. Stuart M. Flechner, kidney transplant specialist and director of the center. He came to Stanford in September from the University of Texas Medical School at Houston, which has one of the largest renal transplant programs in the United States.

Deveney said Ekalook came to Stanford for the operation because her mother was nearby and because of Stanford's reputation for transplant operations.

Operations such as Ekalook's, involving donor organs from relatives, present fewer problems because there is less chance of the body rejecting the transplanted organ.

Stanford pioneered kidney transplants on the West Coast in 1960, but the program was discontinued a decade ago because of space and financial considerations.

Federal financing now makes it feasible to restart the program as part of an expanded emphasis on transplantation at Stanford. Official approval was granted from the federal Health Care Financing Administration (HCFA) after a site visit Oct. 29.

RESEARCHERS SEEK VOLUNTEERS TO AID IN STUDY OF RESPIRATORY DISEASE IN FORMER PREEMIES

STANFORD—

Stanford University researchers will be looking for telltale signs of lung disease in people born prematurely and treated for Respiratory Distress Syndrome (RDS) at Stanford University Hospital between 1964 and 1974.

The three-year study, supported by a $270,000 grant from the National Institutes of Health, will involve individuals 13 to 22 years of age, but the researchers also will need healthy volunteers of the same ages to make scientific comparisons.

"Between 11 to 22 percent of infants with RDS, also known as hyaline membrane disease, who are treated with intensive care techniques, develop a severe chronic lung disease called bronchopulmonary dysplasia (BPD)," said Dr. William H. Northway, Jr., professor of diagnostic radiology and pediatrics at the School of Medicine.

"BPD remains a significant clinical problem for neonatologists throughout the world," emphasized Northway, who will direct the study.

He estimates that as many as 5,500 infants who receive life-saving oxygen therapy in U.S. intensive care nurseries each year develop BPD, and some of them perhaps may continue to have abnormalities of this disease into adolescence.

Some manifestations of this chronic condition may include predisposition to asthmatic attacks and respiratory infections, including repeated pneumonias, Northway explained.

"We wish to know if these individuals have residual lung disease, and if so, to find ways of preventing it and treating it," Northway said.

Ironically, BPD was first discovered by Stanford University researchers led by Northway in 1967, who were battling RDS, a disease expressed during the first hours of postnatal life. In RDS, the tiny air sacs of the premature infant's lungs resist inflation. The future course of these belabored infants was death for most within 72 hours of birth.

"But with oxygen-regulated ventilators and various supportive measures available," Northway said, "most infants who would otherwise have died now recover after being extremely ill for a week or more. These survivors have an excellent chance of developing normally as do premature infants who never had the disease."

Yet there is no denying the fact, Northway added, that breathing oxygen in higher-than-atmospheric concentrations is not what our lungs were meant to do—and certainly not what premature lungs are meant to do. The lungs of infants with BPD showed multiple abnormal cystic changes, including bronchial damage.

Northway credits the Stanford discovery of this problem and the revised criteria of oxygen therapy in the newborn infant for effectively reducing BPD incidence in intensive care nurseries throughout the world. This is especially true in premature infants with birth weights above 1,500 grams.

"The disease, however, continues to be seen in 40 to 50 percent of the infants below 1,000 grams," Northway added, "and how to manage these borderline babies is a real challenge."

The Stanford study will include 28 former premature infants treated at Stanford between 1964 and 1974. Many of the former patients have been notified, Northway said, and have agreed to take part.

But to validate the study's findings with comparisons from a normal population, Stanford researchers would like young healthy volunteers, ages 13 to 22, to take part. They will be matched for age and sex with the former patients and given a physical, which includes a standard pulmonary function test (breathing through a tube), an electrocardiogram, a heart ultrasound examination and a chest X ray. The volunteers will also provide a drop of blood obtained through the fingertip and will fill out a questionnaire.

Each volunteer will be paid $25, but to participate, parents' permission will be required, Northway said.

Individuals interested in volunteering, may contact the study's coordinator Kathy Carlisle at Children's Hospital at Stanford (415) 327-4800, Ext. 208.

STANFORD HOSPITAL BOARD APPOINTMENTS ANNOUNCED

STANFORD—

Dr. Duncan E. Govan, professor of surgery (urology) at the Stanford University School of Medicine, has been named to the Stanford University Hospital Board of Directors.

He was appointed by the general members of the hospital corporation to serve a three-year term beginning Jan. 1. He succeeds Dr. Robert Chase on the board. By-laws provide that one board member be a full-time faculty member.

The terms of Chase, Geraldine Steinberg and W. James Ware all expire Dec. 31. The seats of Steinberg and Ware were left temporarily unfilled.

Board members John Freidenrich and Jack R. Wheatley, whose terms also expire Dec. 31, were reappointed to three-year terms. The 18-member board is comprised of community, medical and lay leaders as well as university faculty and administrators. Twelve of the board members are appointed by the general members of the corporation, who also are trustees of the University.

All of the appointments were made Tuesday, Dec. 9, and announced Wednesday, Dec. 10, at the regular meeting of the Hospital board.

At the same board meeting, University President Donald Kennedy announced that his position as chair of the Hospital Board will be filled by vice-chair Dean Morton during Kennedy's 2 ½-month leave. Kennedy expects to miss only the February meeting of the board.

Govan joined the Stanford faculty in 1961 as assistant professor. He was appointed associate professor in 1964 and professor in 1970. From 1977 to 1980, he was also the associate dean of curriculum at the School of Medicine.

He received his M.D. from the University of Manitody Medical School and a Ph.D. at the University of Chicago. He completed his residency in urology at the University of Chicago School of Medicine.

NEW TOOL HELPS IDENTIFY DISEASE-CAUSING GENES

STANFORD—

A new tool that separates large pieces of DNA from one another could significantly speed scientists' attempts to identify disease-causing genes, according to Stanford University Medical School researchers.

The technique, described in the December 19 issue of *Science*, can accurately separate chunks of DNA—the genetic material of all living things—up to 100 times larger than possible with previous methods, the scientists said.

Since isolation of big pieces of DNA dramatically eases the problem of locating specific genes, the new method should allow scientists to decipher the identity and structure of disease-causing genes much more quickly than ever before, predicted Dr. Gilbert Chu, a research fellow in Dr. Paul Berg's laboratory in Stanford Medical School's biochemistry department. (On Jan. 1, Chu will become an assistant professor in the department of medicine.)

In the last decade scientists have made enormous progress in identifying certain important genes. Despite the progress, the number of known genes represents only a tiny percentage of the total number of existing human genes.

The new technique, which builds on previous advances by Columbia University researchers, is so promising that scientists from around the world have already contacted Chu for information about the special instrument he and his colleagues developed.

The new method may help solve "a broad range of problems," Chu and his colleagues said, including the identification of genes that cause diseases such as muscular dystrophy, cystic fibrosis, and Huntington's disease.

Chu developed the technique in collaboration with Stanford M.D./Ph.D. student Douglas Vollrath and biochemistry professor Dr. Ronald Davis.

The research was supported by grants from the National Institutes of Health and the MacArthur Foundation.

The researchers suggested that the new method could also accelerate efforts to create a genetic "map" of human DNA. Such a map would indicate precise locations for each of the thousands of human -- genes on the genetic superstructures in cells, which are called chromosomes. Such a genetic map would enable scientists to predict an individual's risk of developing many different diseases.

The technique also could be useful for studying sites of chromosome breakage and reattachment. These sites, called translocations, are believed to play a role in causing many types of cancer.

It also appears to be a more accurate method than those now available for isolating intact chromosomes from parasites that cause diseases such as malaria, sleeping sickness, or leishmaniasis, Chu said, and it will aid research on yeast, simple organisms whose cells resemble our own.

The technique improves on standard "gel electrophoresis," the basic method for separating pieces of DNA from one another. Gel electrophoresis works by passing DNA fragments of different sizes through a gel placed in an electric field. The pieces of DNA move through the electric field at different speeds determined by their sizes. The larger pieces move slightly more slowly, becoming separated from the faster small pieces.

But since the difference in speed is relatively small, conventional gels are most useful for studying DNA from viruses and bacteria rather than the "huge stretches" of DNA that often make up human genes, Chu explained.

The conventional devices can reliably separate pieces of DNA that are less than 50,000 base pairs long, he said. (A base pair is the chemical building block of a gene.) This is good for studying viral DNA, which might be on the order of 5,000 base pairs in length, he said.

But since many molecular biologists are moving away from studying viruses and on to more complex organisms, better tools were needed for resolving larger DNA pieces. One yeast chromosome may be about 2 million base pairs long while the average human chromosome is 150 million base pairs long.

The new methods, first suggested by David Schwartz and Charles Cantor of Columbia University, separate DNA pieces up to 5 million base pairs long, a 100-fold improvement. The Columbia researchers developed the idea of switching the direction of the electric field across the gel, making it possible to separate large DNA fragments. But distortions made their results difficult to interpret.

In the new process developed at Stanford, those distortions are eliminated, Chu said.

In the Stanford instrument, the electric field is controlled by a hexagonal array of electrodes to produce what the researchers call a contour-clamped homogeneous electric field (CHEF). In addition, the electric field periodically alternates 120 degrees in direction. Each time the electric field changes direction, the DNA pieces change their direction of movement. The back-and-forth switching causes the DNA to zigzag through the gel. In this case, the larger pieces lag much farther behind the small ones because all the corners of the zigzag pattern slow them down.

"It's like the difference between a bus and a passenger car going down a road with hairpin turns," Chu said. "Both can go fast down the straight parts, but the bus falls farther and farther behind because it crawls around each bend."

The method is not yet powerful enough to separate whole human chromosomes from one another, but the researchers hope that further work may achieve that goal. Although a process called karyotyping already exists, in which microscopic examination of the chromosomes can reveal obvious abnormalities, it is time-consuming and does not provide anywhere near the amount of information that would be available using the new method, Chu said.

TRANSPLANT RECIPIENT, 4, LEAVES HOSPITAL TO VISIT SANTA CLAUS

STANFORD—

Four-year-old Caillie Stufflebeam, Stanford Medical Center's youngest double heart transplant patient, left the hospital for the first time in three months on Tuesday, Dec. 9, to go see Santa Claus.

She and her mother, Janine Stufflebeam, attended the annual Christmas Party for children at the Ronald McDonald House at Children's Hospital at Stanford. Caillie sat on Santa Claus' lap and played with live reindeer.

Cardiologists at Stanford Hospital agreed to let her leave the North Intensive Care Unit long enough for the party after the results of a biopsy showed she was not rejecting the heart she received on Thanksgiving Day.

Caillie, of Seaside, Calif., had not been out of the hospital since her first transplant on Sept. 15. The second transplant became necessary when her body rejected the first donor heart.

Elizabeth Craze, who was 2 years old at the time of her transplant, is the only person younger than Caillie to receive a transplanted heart at Stanford. However, physicians have announced plans to perform transplants on neonates—infants in the first 6 to 8 weeks of life—when there are suitable candidates and donor organs.

HANGOVERS AFFECT PILOTS HOURS AFTER DRINKING

STANFORD—

A "hangover effect" may significantly impair pilots' abilities to perform critical flying maneuvers as long as 14 hours after they stopped drinking alcohol, according to a study by researchers from the Stanford University School of Medicine.

Results of the study were reported in the December issue of the American Journal of Psychiatry by the researchers, Dr. Jerome A. Yesavage, assistant professor of psychiatry, and Von Otto Leirer, a research associate in psychiatry.

The research was conducted at the Palo Alto Veterans Administration Medical Center. It involved 10 Navy pilots from Moffett Field Naval Air Station in California who consumed the equivalent of five to seven 6-ounce glasses of wine, then were tested 14 hours later on a flight simulator. In a control situation, they were tested after going 48 hours without any alcohol.

Although the pilots were unaware of any impairment in their flying abilities, the report stated, "performance was worse in the hangover condition on virtually all measures."

The pilots had no traces of alcohol in their blood at the time of the flight simulation, but all would have been considered legally drunk in many states at the end of a two-hour drinking session 14 hours earlier. All had blood alcohol concentrations higher than a tenth of a gram per deciliter, which is considered as positive evidence of driving while intoxicated in many states.

The pilots regularly fly four-engine P-3C Orion antisubmarine airplanes and the simulated flight conditions included takeoffs and instrument landings with the loss of two engines on one side of the airplane.

"Because the literature we reviewed suggested that the more complex the task studied, the longer the effects, we chose to study a complex flying task," the researchers reported.

Yesavage and Leirer said they were "particularly concerned by the lack of awareness of hangover effects by some pilots....This result replicates prior work from our laboratory in which a series of private pilots were unaware of hangover effects from marijuana. These results are consistent with survey findings indicating that most private pilots think it is all right to fly four hours after drinking some amount of alcohol."

TRUSTEES APPROVE DESIGN OF $73.9 MILLION NEW CHILDREN'S HOSPITAL AT STANFORD

STANFORD—

The Stanford University Board of Trustees Tuesday, Dec. 9, approved the design for a comprehensive New Children's Hospital at Stanford.

The project, expected to cost $73.9 million, is designed by the San Francisco architectural firm of Anshen and Allen. It will include 125 pediatric beds and support services.

"Everything's going on schedule," said Dr. Lawrence G. Crowley, pleased by the trustees' action. Crowley is chairman of the 20-member board planning the New Children's Hospital at Stanford.

Construction is expected to begin sometime in fall 1987, he said.

The new children's hospital will be financed principally by gifts. One of these is a $70 million pledge from Lucile and David Packard, one of the largest commitments from a private donor in Stanford's history.

The gift "will help establish one of the foremost comprehensive centers for pediatric care, research, and training in the country," Stanford President Donald Kennedy said when the pledge was announced last May.

The Packard pledge will provide $40 million for the design, construction and equipment costs of the project. The remainder will complement university efforts to modernize Stanford University Hospital, including perinatal facilities, and pediatric academic space for the Stanford University School of Medicine.

The present Children's Hospital at Stanford will contribute $5 million, and a community campaign will seek $20 million in gifts toward the children's hospital project.

The four-story structure, connected to Stanford University Hospital, will enable Stanford and Children's to consolidate inpatient and outpatient pediatric services now housed in separate locations at some distance from each other.

It will include 94 medical-surgical beds and a 31-bed neonatal intensive care unit. Adjacent to the latter will be a new labor and delivery suite for Stanford University Hospital's obstetrical service. A well-baby nursery and about 50 medical-surgical beds for mothers in Stanford University Hospital will be closely linked to the labor and delivery suites. The placement of these units adjacent to each other will provide an important new perinatal service for mothers and children.

Included in the new building will be the Stanford Children's Ambulatory Care Center, which provides 27 separate clinical services, a day hospital, an auditorium, cafeteria and clinical and diagnostic X-ray laboratories. An adjoining two-level parking structure will be located between the hospital building and Welch Road.

The new facility will be the medical school's principal hospital for clinical practice, research, and teaching related to children's medical and health care. Stanford and Children's have been operating joint programs for many years under the medical direction of the Department of Pediatrics.

Although the new hospital will be an integral part of the Stanford University Medical Center, it will be governed by a separate and independent board.

Anshen and Allen, the architects, have designed a building that will be "as non-threatening and non-institutional as possible," explained project director Langston Trigg, Jr.

The building uses stepped back terraces to break down a bulky appearance so common in many structures, he said. The entrance and drop off point are actually one story high in scale. "Attention throughout the building has been paid to the varying heights and perspectives of children and adults," he added.

One feature is the way functions are assigned to various levels of the building. For example, the second floor brings together several functions to support the concept of a Maternal-Infant Care Center.

"Terraces and garden courts are a key feature in the integration of natural elements into the building," Trigg said. "They provide a pleasing environment and accomodate functions such as therapy and recreation."

A large courtyard will serve as a central orientation feature, he said, and planting will feature a variety of trees, green plants, flowering plants and grass.

Automobile access to the New Children's Hospital will be from Welch Road when it is completed in 1989.

STANFORD UNDERGRADUATE BECOMES FIRST HEART TRANSPLANT RECIPIENT TO QUALIFY AS PILOT

STANFORD—

Andrew Craze said he was pretty nervous Monday, Dec. 8, but not because he was making medical history.

The 19-year-old Stanford sophomore had already become the first heart transplant recipient to qualify medically as a pilot. On Oct. 20, he was sent a third-class airman medical certificate. So on Monday, it was time for his first solo flight.

Encouraged by his Stanford Flying Club instructor, Robert Petersen, Craze, of Cleveland Heights, Ohio, got into the cockpit of a club-owned Cessna-150, taxied down the Palo Alto Airport runway, and then, in about 30 minutes alone in the plane, he made the three takeoffs and landings that qualified him for his private pilot's license.

That Craze was the first heart transplant recipient to receive medical clearance for flying was confirmed by Dr. William H. Hark, manager of the Aeromedical Standards Division of the Federal Aviation Administration in Washington, D.C.

Craze's medical certification, which was gained with the help of members of Stanford's Department of Cardiovascular Surgery, is unrestricted and was issued by Dr. Frank H. Austin Jr., federal air surgeon.

Unlike many young, new pilots — but similar to airline pilots — Craze will have to renew his medical certification every six months instead of once every two years. He is also required to report any changes in his condition to the FAA.

Like all new pilots, Craze's solo license allows him to fly a plane alone. Until he qualifies further, he cannot carry passengers and must continue to have cross-country flight plans approved by an instructor.

Unfortunately, Craze, who received his transplant at Stanford July 10, 1983, is not unique, medically, from other members of his family. His sister, Elizabeth, became Stanford's youngest heart transplant patient ever on Oct. 8, 1984, at the age of 2½.

Both Crazes suffered from cardiomyopathy, a deterioration of the heart muscle that appears to run in families. Craze's parents, Susan and Charles, had already lost a son and a set of female twins to cardiomyopathy when Andrew's once fatal diagnosis was made a few months before his operation.

The cause of cardiomyopathy is not precisely known, but Stanford heart transplant physicians believe that some people inherit an almost fatal sensitivity to a virus that is harmless to most people.

"I like to consider myself a fairly normal person," said Craze, as he stepped out of the Cessna after his historic flight.

Bert J. Postma, director of the Stanford Flying Club, said Craze qualified in training "a bit faster than average." But then, Postma said, club officials were surprised that his medical certification was delayed. It was then, said Postma, that Craze told fellow club members that he had had a transplant and would require more documentation than average to secure his medical certificate.

Craze, an undeclared major deciding between physics and engineering, said his father had gotten him interested in flying. Charles Craze had taken flying lessons but never completed the course to receive a solo license.

Andrew, who became interested in attending Stanford when he visited the campus while preparing for his transplant procedure, started taking flying lessons from the campus club soon after he arrived as a freshman in 1985.

His goals now include seeking a full license that will allow him to carry passengers.

Some 425 persons have received heart transplant operations at Stanford since the program began in 1969. Recently most are returning to productive lives, including Andrew's sister, who is attending nursery school, can count to 109, and enjoys making snow scenes with powdered sugar, according to her mother.

VANDERBILT SURGEON LECTURES AT STANFORD

STANFORD—

Dr. H. William Scott, professor emeritus of surgery at Vanderbilt University, is the 1986 Louis and Dorothy Kovitz Visiting Professor at Stanford University Medical Center.

Scott, whose interests include surgery for peptic ulcer, endocrine surgery, and obesity, will deliver his talk at 4:30 p.m., Friday, Dec. 12, in Fairchild Auditorium at the Medical Center. His topic is "Cushing's Syndrome—The Vanderbilt Experience."

Major organizations Scott has served as president include the American College of Surgeons, the International Society of Surgery, the American Surgical Association, and the Society of Clinical Surgery.

The author of more than 300 publications, Scott served on the faculty of the Nashville, Tenn. medical school from 1952 to 1982 and currently serves as surgeon-in-chief emeritus.

The Kovitz visiting professorship was established in 1970 in honor of the late Dr. Louis Kovitz and his wife, Dorothy. The purpose of the professorship is to allow physicians of national or international prominence to give annual lectures, rounds and clinical pathological conferences on topics of medicine and surgery at Stanford.

The lectureship is sponsored in alternate years by the Medical School departments of Surgery and Medicine.

PATIENT RELATIONS ASSOCIATES OFFER SPECIAL KIND OF FRIENDSHIP

STANFORD—

When patients need the friendship that neither physicians or family have time to provide, patient relations associates may be the people who best fill the bill.

Patient relations associates "provide a liaison between patients and their families, on the one side, and the institution's staff and administration on the other," said Jeanne Kennedy, Stanford University Hospital director of community and patient relations. She described the hospital's program, which includes 25 volunteer patient relations associates, in an article in the current issue of *Perioperative Nursing Quarterly*.

Medical knowledge and the power of medical technology have advanced dramatically in the last few decades, she said. While this has led to improved treatment, it has also led to an increased lack of understanding for patients and their families. "Technology and medical specialization have fragmented patient care and made it difficult for hospital staff to respond to patients in a personal way," she said.

Patient relations associates can help compensate. They started appearing in hospitals in the late 1950s; now more than 3,300 hospitals offer their services to patients and staff, Kennedy said. A national organization, the American Hospital Association's National Society of Patient Representatives formed in 1972.

At Stanford, the patient relations staff are advocates and problem solvers, Kennedy continued. "Their responsibilities are to relieve the anxieties of patients and their families, to provide a single referral service and to give the hospital administration the information it needs to rectify problems.

"Patient relations interactions are not confrontational; the representative is not on anyone's side," she explained. "Rather, the representative's goal is to solve the problem to everyone's satisfaction."

For example, orthopedic nurses were having difficulty dealing with one patient who was threatening and abusive. After he threw a glass at one of the nurses, a patient relations associate was called. She found out he was a football player whose knee injury had put an end to his career. That understanding made the rest of his stay much more pleasant.

Another patient expressed a desire for a boysenberry pie. After checking with the appropriate people, a patient relations associate delivered one, which made all the difference to the patient.

It takes no formal skills to be a patient relations associate, Kennedy explained, but rather the "maturity and breadth of experience that allows them to understand what is going on with people in crises." A sense of empathy, interpersonal skills and good judgement are desired traits as well.

SUH's patient relations associates go through a 24-hour training and orientation course upon acceptance to the program, followed up by a four-to six-week preceptorship and monthly training updates. Some patient relations tips include touching patients in greeting and farewell; identifying oneself clearly; treating patients as colleagues and anticipating patients' needs. Even if patients are sedated, Kennedy noted, their knowledge of these seemingly small acts make a large difference in their well-being.

FLIGHT SIMULATOR-LIKE COMPUTER MAKES EMERGENCY PHYSICIANS SWEAT

STANFORD—

A computer system that functions like an airline flight simulator is making medical students and even experienced emergency physicians and nurses sweat as they learn.

"You really feel the pressure, and that's what makes it realistic and helpful," said Dr. Ricardo Martinez, director of clinical services for the Emergency Department at Stanford University Hospital. He's talking about the DxTER Clinical Simulator System, a computer package which he feels is helping to solve one of medicine's most difficult dilemmas—how to teach medical students and physicians new skills in lifesaving techniques without putting patients at risk.

Fourth year Stanford medical student Lavern Bentt ran into DxTER in the medical school library's media center while on vacation.

"I came back for several days, several hours at a time and really got into the system," said Bentt, from Jamaica, N.Y. She said it was extremely realistic and accurate and helpful during her subinternship in surgery.

Each time she sat down, Bentt selected one of six case studies available on the system's integrated videodisc and computer program. The videodisc rolling, Bentt watched as professional actors unfurled a scenario. A doctor and nurse chatted, and suddenly their calm was shattered with the arrival of a trauma patient.

An actor playing a paramedic explained what he knew about the patient. The actors listened, and so did Bentt. Her job, by touching preselected points on the videoscreen, was to tell those actors what to do next for the patient.

She could order tests, provide medication, and do virtually anything a doctor or nurse would do in a real situation. And the TV screen flashed the appropriate dramatized response. Then she watched the patient respond to her care.

Do the right thing, and the patient is stabilized and able to be transferred out of emergency. Do something really wrong, and the videodisc whirs briefly and flashes an image of a patient actor suddenly gone limp.

more

"The patient has stopped breathing, doctor," said the nurse. "What are you going to do?" The choice was Bentt's. As a digital clock ticked off precious seconds on the screen, she had to take appropriate action. If she waited too long, the doctor and nurse would return to the screen to inform her that the patient died. Everything happens in "real time." If you need information from a blood test, it's going to take 30 minutes. Everything which could happen to a real patient while waiting for results can happen to the DxTER patient.

As Martinez put it: "The medical student or intern or nurse gets to make real decisions and real mistakes without threatening a patient.

"Knowledge from books and lectures is relatively easy to come by, but it's much more difficult to teach students or new physicians how to make critical judgments in a clinical setting in a realistic period of time.".

Bentt remembers one scenario in which she forgot to insert a nasal gastric tube. The computer took note, and the patient aspirated and died.

"I don't think I'll ever overlook that again," Bentt said later. "And I'm grateful it wasn't a real patient."

The DxTER system was developed by Dr. David Allan, a San Diego pediatrician, who said he began to realize the limitation of lectures while serving more than four years ago as associate dean for postgraduate education at the University of California at San Diego.

"Dealing with somebody who has a motor vehicle accident is a very emotional experience, so it's vital to include the human tension in the learning environment," Allan said in a telephone interview.

"There's a lot of evidence that the more emotion you generate in a learning situation, the better the educational experience is going to be," said Allan.

And Martinez agrees that knowledge is one thing, judgment is something else. "This system tests your ability to use judgment with the knowledge you bring."

Allan is now president of a San Diego computer company, Intelligent Images, which makes DxTER.

About 25 DxTER systems are being tested, half in medical schools and half in community hospitals.

Anne Brewer, media librarian at Stanford Lane Medical Library Fleischmann Learning Resource Center, said the library agreed to place a DxTER system in the learning center several months ago on a test basis,"and the response has been enthusiastic from both faculty and students. Everyone seems to agree it's uniquely helpful."

Allan said the tool is useful for smaller hospitals because it can be placed right in the emergency department, where doctors and nurses can practice when they have a free moment. Via the video computer, they have an opportunity to practice on serious trauma cases which in real life they must respond to quickly but only rarely.

more

3-3-3

And nurses, said Allan, are very much a part of the process, including the vignettes. When a user makes a mistake, it is often the nurse who stares out from the video screen and says, "Doctor, are you sure you want to do that?"

At the end of each scenario, the computer compares the user's work with how a panel of experts managed the patient under similar circumstances. The analysis includes not only medical management but also cost. Every time a test or service is ordered, DxTER takes note of the price. At the end, the user finds out not only how much has been spent, but also how much in terms of dollars and tests an expert panel thought was optimal. (Failure to order a necessary test is a worse no-no).

The videodisc also includes formal instruction, which users can study before trying their hand on a patient.

The guts of the system includes an IBM PC linked to a videodisc player. Because of the large data base available, the lesson can branch in many different ways. Different endings, usually four, have been programmed into the lesson, and the result is dependent on how the learner manages the patient.

At $12,000 for the hardware and programs for the first 12 cases, "we're not exactly in the video game business," said Allan. The cost, he said, is reasonable as a working tool for a community hospital and can become even more economical when additional scenarios are developed for other uses, such as personnel education. Plans call for disks in hospital employee education, which can be used by individuals for their own education and to fulfill accrediting agencies' continuing education requirements.

Martinez said he hopes to have a DxTER system as a fixture in the emergency department (Stanford's gear is located in the Learning Resources Center). And he's hoping for more scenarios for people he supervises and for his own continuing education.

Martinez, who is residency trained in emergency medicine, said, "a lot of decisions are based on subtleties. Two patients may come in with identical symptoms but entirely different problems. Constant practice ensures you'll be able to get down to the guts of the problem, and tools such as DxTER help."

The batch of 16 programs currently available or under active development include such titles as "Abdominal Stab Wounds," "Chest Traumas," "Diagnostic Decisions," "Shotgun Wound to the Abdomen," "Initial Assessment of Respiratory Difficulties," "Adult Respiratory Distress Syndrome," "Chronic Obstructive Pulmonary Disease," "Discontinue Mechanical Ventilation," "Basic Neurological Assessment," "Closed Head Trauma," "Coma of Unknown Origin," and"Spinal Cord Injury."
